

# Centennial Celebration and Congress of the International Union of Soil Sciences

Florence - Italy  
May 19 - 21, 2024

## ABSTRACT BOOK

Under the Auspices:

# COMMITTEES

## Congress Presidents

Giuseppe Corti

Edoardo A.C. Costantini

Sara Marinari

## Organising Committee

Alberto Agnelli

Filiberto Altobelli

Anna Benedetti

Annamaria Bevivino

Antonello Bonfante

Alessandro Buscaroli

Costanza Calzolari

Tommaso Chiti

Stefania Cocco

Luigi P. D'Acqui

Lorenzo D'Avino

Carmelo Dazzi

Mauro De Feudis

Claudia Fontana

Michele Freppaz

Vito Armando Laudicina

Giuseppe Lo Papa

Grazia Masciandaro

Giovanni Mastrolonardo

Stefano Mocali

Giacomo Pietramellara

Simone Priori

Claudio Zaccone

Claudio Zucca

## Scientific Committee

Costanza Calzolari

Claire Chenu

Stefania Cocco

Giuseppe Corti

Edoardo A.C. Costantini

Paul Hallett

Richard Heck

Rainer Horn

Eugene F. Kelly

Giuseppe Lo Papa

Sara Marinari

Stefano Mocali

Cristine Morgan

Laura Bertha Reyes Sánchez

Natalia Rodriguez

Ren Fang Shen

Xin Song

Claudio Zaccone

Jiabao Zhang

Yongguan Zhu

# GENERAL THEMES

## *Soil health in achieving the Sustainable Development Goals*

Soil health is defined as “the ability to sustain productivity, diversity and environmental services of terrestrial ecosystems”, extending the significance of soil health far beyond the historically concepts of soil fertility and soil quality, including human health and sustainability goals for planetary health. Thus, it will significantly contribute to reaching the targets of the following Sustainable Development Goals (SDGs): SDG 2 (zero hunger); SDG 3 (Health); SDG 6 (clean water and sanitation); SDG 12 (sustainable consumption and production); SDG 13 (climate action) and SDG 15 (life on land).

However, several issues have to be addressed to achieve such goals. For example: Defining soil health indicators, Dynamics and functional role of soil biodiversity, Harmonizing soil monitoring strategies, Soil pedodiversity and biodiversity, Soil legacy effects.

## *Soil governance*

Soil is a non-renewable resource. Its use requires policies, strategies, and processes of decision-making at the local, national and supra-national level.

Governing the soil requires international and national collaboration between governments, local authorities, industries, research institutions and citizens to ensure implementation of coherent policies that encourage practices and methodologies that regulate the soil's use to avoid conflict between users to promote and ensure soil security and sustainable land management. Coherent soil governance is the foundation for promoting sustainable agriculture and ensuring food security in addition to all essential ecosystem services.

Under this theme, different sessions could address issues like: Soil Security, Soil Policies, Soil Economy, Soil ecosystem Services, Soil and Education, Soil Awareness, Soils and Societal Development, Sustainable Soil Management, Sustainable Agriculture, Participatory processes in Soil Conservation, Soil Role in Food and Water Security, Soils as Cultural Heritage, Soils and Landscape Management, Soil Partnerships, Living Labs and Lighthouses.

## *Soil in the circular economy*

Circular economy is an economic system focused on maximizing the reuse of natural resources and products, minimizing their depreciation. We consider the soil a natural resource as the water. As the formation of topsoil and the recovery of land and soil quality are extremely slow processes, they are considered as non-renewable resources. Therefore, the recovery and reuse of land and soil is necessary to secure future provision of natural resources and services for the growing world population.

Soil plays an important role in the circular economy as, for instance, the provider of space for societal activities to take place. It stores the stock of mineral resources and offers possibilities for producing biobased resources to replace the use of mineral resources.

Soil's role in the biogeochemical cycles is very important for closing the cycles of water and nutrients. The use of natural cycles as ecosystem services is efficient in reducing the implementation of resource-intensive technical practices.

# GENERAL THEMES

## *Soil sciences impact on basic knowledge*

Soil consists of a three-phases system containing solids, liquids and gases that strongly interact with each other in the pedogenic processes. Mineral fragments, organic matter, and soil air evolve through a series of biological activities, chemical reactions, and physical forces that are influenced by different environmental factors.

Soil health refers to the capacity of soil to sustain or improve productivity, plant health, and higher trophic levels, as well as air and water quality in natural and managed ecosystems. Interdisciplinary knowledge of chemistry, physics, atmospheric science, soil science, biology, natural history, and ecology is needed to recognize the role of soil in regulating greenhouse gases, reducing nutrient export from agricultural land, controlling pests, and supporting biodiversity that provides many ecosystem services to society.

## *Soil in the digital era*

Soil information technology supports many research fields including pedology, landscape modeling, natural resources management, land evaluation, land use planning, carbon storage, land use/land cover change, environmental risk assessment and modeling and smart/precision farming. There is increasing demand for soil information as it relates to: location, quality and quantity of soil properties, processes and interactions with various natural resources.

Under this theme, different sessions could address issues like: Digital Soil Mapping, Pedometrics, Geostatistics, Soil Spatial Variability, Soil Information Systems, Soil Spatial Infrastructures, Decision Support Systems, Soil Modeling, Environmental Modeling and risk assessment, Soil Proximal Sensing, Soil Remote Sensing, Soil Management in Smart Farming, Mapping and Modeling of Soil Ecosystem Services, Mapping and Modeling of Soil Threats, Soil use and climate change modelling.

## *Soil and humanity*

Soils underpin, directly or indirectly, most of the ecosystem services defined as the benefits humanity obtains from ecosystems. Soil scientists have the responsibility to make clear to civil society, policy makers, scientists and experts in other disciplines the overwhelming importance of soil in their lives.

This implies the need for integrating soil sciences in education at all levels and for increasing soil awareness of general public. A well informed society will have the possibility to exploit the numerous functions soil provides while sustaining the continuous provision of ecosystem services. Under this theme, different sessions could address issues like: soil and humanistic disciplines – history, philosophy, sociology, art, religion; soil and human health, soil and sustainable and liveable cities, soil security and land grabbing, soil education and promotion, soil and human rights.

# GENERAL THEMES

## *Equity, diversity, and inclusivity in soil sciences*

Globally, women play a substantial role in agriculture and strong linkages between sustainable soil management (SSM) and gender equality have been demonstrated. However, a number of cultural and social constraints exist which hinder a full recognition of women's role in SSM. An insufficient soil education is one of them. Besides, local soil knowledge, often women driven, is nowadays considered a tool for a sustainable soil management. Despite some encouraging signals, women are still underrepresented in soil science, and in particular in leadership positions and in awards rates.

Supporting equity, diversity and inclusivity in soil science is a key issue for addressing fundamental scientific questions and societally relevant environmental challenges.

Under this theme, different sessions could address issues like: Women in soil science, Underrepresented minorities in soil sciences and soil-related scientific societies, Local knowledge and SSM, Soil education tailored on women and on local/indigenous communities, Ethnopedology.

# SESSIONS

## 1. EQUITY, DIVERSITY, AND INCLUSIVITY IN SOIL SCIENCES

### **131441 - BOOSTING GLOBAL SOIL SCIENCE COLLABORATION: FOSTERING EQUITY, DECOLONIZATION, AND CAPACITY STRENGTHENING**

LEAD CONVENER:

W. WIDYATMANTI – Universitas Gadjah Mada, Sleman, INDONESIA

CO-CONVENERS:

B. MINASNY – University of Sydney, Sydney, AUSTRALIA

I.S. LIGOWE – Chitedze Agricultural Research Station, Lilongwe, MALAWI

### **133426 - GENDER INEQUALITIES AND SOIL HEALTH**

LEAD CONVENER:

L. FORSYTHE – Natural Resources Institute, University of Greenwich, Chatham, UNITED KINGDOM

CO-CONVENERS:

L. BUCHI – Natural Resources Institute, University of Greenwich, Chatham, UNITED KINGDOM

A. MARTIN – Natural Resources Institute, University of Greenwich, Chatham, UNITED KINGDOM

M. PEREZ – Natural Resources Institute, University of Greenwich, Chatham, UNITED KINGDOM

### **133511 - MOVING TOWARD DIVERSITY, EQUITY, AND INCLUSIVITY IN SOIL SCIENCE SOCIETIES**

LEAD CONVENER:

L.B. REYES-SÁNCHEZ – IUSS and National Autonomous University of Mexico, and University of Florida, Soil, Water & Ecosystems Sciences Dept., Gainesville, USA. DAROUB

S. DAROUB – IUSS and National Autonomous University of Mexico, and University of Florida, Soil, Water & Ecosystems Sciences Dept., Gainesville, USA

CO-CONVENERS:

R. M. POOCH – ITPS of GSP-FAO and Spanish Soil Science Society

S. CHAPMAN – Soil Science Society of America, Madison, USA

S. GRUNWALD – University of Florida, Soil, Water & Ecosystems Sciences Dept., Gainesville, USA

T. CARTER – US Dept of Agriculture National Resources Conservation Service (USDA-NRCS), Lincoln, USA

## 2. SOIL AND HUMANITY

### **124495 - YOUTH DIGGING – THE PROGRESS OF EARLY CAREER GLOBAL SOIL RESEARCH**

LEAD CONVENER:

B. GLINA – Department of Soil Science and Microbiology, Poznan university of Life Sciences, Poznan, POLAND

CO-CONVENER:

A. CERÓN GONZÁLEZ – National Autonomous University of Mexico, Mexico City, MEXICO

### **129339 - THE DEVELOPMENT OF SOIL SCIENCE IN THE IUSS COUNTRIES: 100 YEARS OF HISTORY**

LEAD CONVENER:

C. DAZZI – University of Palermo, Palermo, ITALY

CO-CONVENERS:

E.A.C. COSTANTINI – IUSS, Florence, ITALY

K-H. FEGER – University of Dresden, Germany

T. KOSAKI – University of Tokyo, Japan

### **129617 - SOIL HEALTH FROM MULTIPLE PERSPECTIVES**

LEAD CONVENER:

R. JANKE – Kansas State University, Manhattan KS, USA

CO-CONVENERS:

D. PINDELL – Olympic College, Bremerton, USA

J. IBBINI – Hashemite University, Zarqa, JORDAN

P. WATTS – Ecoartspace Organization, Santa Fe, USA

### **129928 - SOIL SCIENCES ENTERING INTO TRANSDISCIPLINARY RESEARCH**

LEAD CONVENER:

M. KAISER – University of Bergen, Bergen, NORWAY

CO-CONVENER:

M. PARADISO – University of Naples, Naples, ITALY

### **132213 - SOIL AND LITERATURE**

LEAD CONVENER:

R.M. POCH – Universitat de Lleida, Lleida, SPAIN

CO-CONVENER:

E.A.C. COSTANTINI – IUSS, Florence, ITALY

### **132332 - SOIL SCIENCE AND GEOETHICS: CONTRIBUTING TO CREATE A MORE SUSTAINABLE SOCIETY**

**LEAD CONVENER:**

S. PEPPOLONI – National Institute of Geophysics and Volcanology / International Association for Promoting Geoethics – IAPG, Rome, ITALY

**CO-CONVENERS:**

A. KRZYWOSZYNSKA – University of Oulu – IAPG, Oulu, FINLAND

G. DI CAPUA – National Institute of Geophysics and Volcanology / International Association for Promoting Geoethics – IAPG, Rome, ITALY

### **132746 - SOILS FOR PLANNING SUSTAINABLE CITIES**

**LEAD CONVENER:**

R. PARADELO NÚÑEZ – Universidade de Santiago de Compostela, Santiago de Compostela, SPAIN

**CO-CONVENERS:**

F. FERRINI – Università degli Studi di Firenze, Firenze, ITALY

M. BONVEHI ROSICH – Harvard University, Cambridge, USA

G. MASTROLONARDO – Università degli Studi di Firenze, Firenze, ITALY

### **133512 - CHILDREN AND YOUNG PEOPLE SAY PRESENT AT THE IUSS CENTENARY CELEBRATION**

**LEAD CONVENER:**

L.B.. REYES-SÁNCHEZ – IUSS and UNAM, Cuautitlán Izcalli, MEXICO

**CO-CONVENER:**

R. HORN – Kiel University and IUSS former President, Kiel, GERMANY

### **133548 - MICROBIOME AS A COMMON THREAD FROM SOIL TO HUMAN HEALTH: INTERACTION, IMPACT AND ROLE OF SOIL-PLANT-HUMAN MICROBIOME AS A NEW CHALLENGE OF INNOVATIVE AGRICULTURE AND QUALITY FOOD**

**LEAD CONVENER:**

V.M. SELLITTO – University of Agricultural Sciences and Veterinary Medicine of Banat, Timisoara, ROMANIA

**CO-CONVENER:**

S. MOCALI – Centro di ricerca Agricoltura e Ambiente (CREA-AA), Firenze, ITALY

### **133559 - SOIL LITERACY, COMMUNICATION AND CITIZEN ENGAGEMENT**

**LEAD CONVENER:**

E. MERLONI – Area Europa scarl, Bologna, ITALY

**CO-CONVENER:**

D. MARAZZA – University of Bologna, Bologna, ITALY

D SAUER – University of Goettingen, Goettingen, GERMANY

### **133574 - SOIL AND WATER CONSERVATION ISSUES WORLDWIDE: FROM THE PAST TO THE FUTURE**

**LEAD CONVENERS:**

C. DAZZI and E.A.C. COSTANTINI (IUSS)

**CO-CONVENERS:**

L. ØYGARDEN and G. LO PAPA (ESSC)

D. NING and J. RUBIO (WASWAC)

C.S. RENSCHLER and I. PLA SENTIS (ISCO)

### **133584 - SOILS IN ARCHAEOLOGY**

**LEAD CONVENER:**

C. NICOSIA – Dipartimento di Geoscienze, Università di Padova, Padova, ITALY

**CO-CONVENERS:**

F. POLISCA – Dipartimento dei Beni Culturali, Università di Padova, Padova, ITALY

D. SAUER – University of Göttingen, Göttingen, GERMANY

### **133597- SOIL, SOUL AND SOCIETY: TRANSFORMATIVE PATHWAYS IN SOIL CARE PRACTICES**

**LEAD CONVENER:**

A. L'ASTORINA – IREA CNR, Milano, ITALY

**CO-CONVENERS:**

L. COLUCCI GRAY – University of Edimburgh, Edimburgh, UNITED KINGDOM

C. COLELLA – IREA CNR, Milano, ITALY

E. CALASTRI – University of Milano, ITALY

V. GRASSO – Bioeconomy Institute-CNR, Sesto Fiorentino, ITALY

### **133604 - HISTORIES OF INTERNATIONALIZATION OF SOIL SCIENCE**

**LEAD CONVENER:**

N. UJHÁZY – School of Geography – University of Nottingham, Nottingham, UNITED KINGDOM

**CO-CONVENERS:**

L.M. CHABALA – School of Agricultural Sciences – Department of Soil Science – University of Zambia, Lusaka, ZAMBIA

R.M. LARK – School of Biosciences – University of Nottingham, Nottingham, UNITED KINGDOM

M. HEFFERNAN – School of Geography – University of Nottingham, Nottingham, UNITED KINGDOM

A. KRZYWOSZYNSKA – Faculty of Humanities, University of Oulu, Oulu, Finland

### **133605 - EPISTEMOLOGIES AND ONTOLOGIES OF SOIL: TOWARDS NEW POLITICS OF SOIL KNOWLEDGE**

**LEAD CONVENER:**

C. BOYER – International Center for Research on Environment and Development, AgroParisTech, Paris, FRANCE

**CO-CONVENER:**

T. LAW – Development Studies, Cornell University, Ithaca, USA

### **133780 - SOIL AS A CULTURAL HERITAGE: THE SOIL KNOWLEDGE AS A HERITAGE FOR THE FUTURE GENERATIONS.**

**LEAD CONVENER:**

M. FANTAPPIÈ – CREA, Firenze, ITALY

**CO-CONVENERS:**

R. BARBETTI – CREA, Firenze, ITALY

D. SAUER – University of Göttingen, Göttingen, GERMANY

R. POCH – University of Lleida, Lleida, SPAIN

S. MANTEL – ISRIC World Soil Information

### **134978 - SUITMA (SOILS OF URBAN, INDUSTRIAL, TRAFFIC, MINING AND MILITARY AREAS)**

**LEAD CONVENER:**

K-H. J. KIM – University of Seoul, Chair of working group SUITMA

**CO-CONVENERS:**

P. CHARZYŃSKI – Nicolaus Copernicus University, vice-chair of SUITMA

W. BURGHARDT – University Duisburg-Essen, co-founder of SUITMA

### 3. SOIL GOVERNANCE

#### **133567 - SOIL AND WATER CONSERVATION: WATER- DRAINAGE AND IRRIGATION STRATEGIES: FROM SECURING PRODUCTION TO PROTECTING ENVIRONMENT**

LEAD CONVENER:

L. ØYGARDEN – NIBIO, Aas, NORWAY

CO-CONVENER:

D. DEC – Facultad de Ciencias Agrarias Alimentas, Univ. Austral de Chile, Valdivia, CHILE

#### **133591 - IMPACT OF GLOBAL TRADE OF FOOD, FEED AND FIBER (3FS) ON SOIL C AND N DYNAMICS, GHG EMISSIONS AND LAND USE CHANGES**

LEAD CONVENER:

D. CHEN – University of Melbourne, Melbourne, AUSTRALIA

CO-CONVENERS:

I. YOUNG – King Abdullah University of Science and Technology, Thuwal, SAUDI ARABIA

M. LENZEN – University of Sydney, Sydney, AUSTRALIA

G. FENG – USDA-Agricultural Research Service, Mississippi State, USA

S.K. LAM – University of Melbourne, Melbourne, AUSTRALIA

#### **133724- INDUSTRY, POLICY AND SCIENCE: WORKING TOGETHER FOR MEANINGFUL SCALING OF SOIL ASSESSMENT AND CLIMATE MITIGATION**

LEAD CONVENER:

A. WICK – Syngenta Group, Fargo, USA

#### **133729 - NITROGEN USE EFFICIENCY AS INFLUENCED BY THE MICROBIOME**

LEAD CONVENER:

A. WICK – Syngenta Group, Fargo, USA

CO-CONVENER:

C. SCREPANTI- Syngenta Group, Stein, SWITZERLAND

#### **133775 - SOIL GOVERNANCE: BUILDING ON STAKE-HOLDERS INTERACTIONS AND INVOLVEMENT FOR A SUSTAINABLE MANAGEMENT OF SOILS**

LEAD CONVENER:

M. FANTAPPIÈ – CREA, Firenze, ITALY

CO-CONVENERS:

C. CHENU – INRAE, Paris, FRANCE

S. KESTRA – WR, Wageningen, THE NETHERLANDS

F. POINÇOT – Acta / RNEST, Paris, FRANCE

## 4. SOIL HEALTH IN ACHIEVING THE SUSTAINABLE DEVELOPMENT GOALS

### 123826 - SOIL SCIENCE LESSONS FROM 100 YEARS OR MORE OLD EXPERIMENTS

LEAD CONVENER:

B. MAHARJAN – University of Nebraska-Lincoln, Scottsbluff, USA

### 124990 - TOWARDS HARMONIZED SOIL HEALTH MONITORING. NOVEL METHODS AND PERSPECTIVES AND SCIENTIFIC, INSTITUTIONAL, AND SOCIETAL CHALLENGES

LEAD CONVENERS:

C. ZUCCA – Università degli Studi di Sassari, Sassari, ITALY

M. MENON – University of Sheffield, UK

CO-CONVENERS:

S. SAIA – Università degli Studi di Pisa, Pisa, ITALY

G. HERNANDEZ RAMIREZ – University of Alberta, CANADA

### 125012 - MATCHING FOOD SECURITY AND ENVIRONMENTAL GOALS: PHOSPHORUS, A KEY GLOBAL ELEMENT

LEAD CONVENER:

F.O. GARCIA – Consultant, Balcece, ARGENTINA

CO-CONVENER:

L. GATIBONI – Associate Professor, Raleigh, USA

### 131145 - DYNAMICS AND FUNCTIONS OF SOIL ORGANIC MATTER UNDER NEW AND TRADITIONAL AMENDMENTS

LEAD CONVENER:

C. PLAZA – Consejo Superior de Investigaciones Científicas, Instituto de Ciencias Agrarias, Madrid, SPAIN

CO-CONVENERS:

B. GIANNETTA – University of Verona, Department of Biotechnology, Verona, ITALY

C. ZACCONE – University of Verona, Department of Biotechnology, Verona, ITALY

### 131649 - THE CENTRALITY OF ORGANIC CARBON IN BALANCING THE MULTIFUNCTIONAL NATURE OF SOILS FOR SUSTAINING HUMAN AND PLANETARY HEALTH

LEAD CONVENER:

B. MINASNY – The University of Sydney, Sydney, AUSTRALIA

CO-CONVENERS:

C. RUMPEL – CNRS, Paris, FRANCE

P. KOPITKE – The University of Queensland, Brisbane, AUSTRALIA

**132182 - SOIL MICROBIOMES – IMPORTANCE FOR CLIMATE RESILIENT FUTURE, DEGRADED LANDS RESTORATION AND PLANT HEALTH CONTROL**

LEAD CONVENER:

M. FRAC – Institute of Agrophysics, Polish Academy of Sciences, Lublin, POLAND

CO-CONVENERS:

A. ACEDO – Biome Makers Inc, West Sacramento, USA

E. KANDELER – University of Hohenheim, Stuttgart, GERMANY

**132261 - ECOSYSTEM SERVICES PROVIDED BY NEMATODES AND OTHER SOIL INVERTEBRATES AND SPECIFIC PROTECTION GOALS**

LEAD CONVENER:

B. MANACHINI – University of Palermo Dept. SAAF, Palermo , ITALY

CO-CONVENERS:

W. BERT – University of Gent, Gent, BELGIUM

S. LANDI – Council for Agricultural Research and Agricultural Economy Analysis(CREA), Firenze, ITALY

A. CEREVKOVA – Institute of Parasitology, Slovak Academy of Sciences (SAS), Kosice, SLOVAK REPUBLIC

**133435 - OPTIMIZATION OF PLANT-SOIL-MICROBE INTERACTION UNDER CROP DIVERSIFICATION**

LEAD CONVENER:

S.I. PATHAN – Università degli Studi di Firenze, Firenze, ITALY

CO-CONVENERS:

N. GENTSCH – Leibniz Universität Hannover, Hannover, GERMANY

G. PIETRAMELLARA – Università degli Studi di Firenze, Firenze, ITALY

**133521 - CARING FOR MOUNTAIN SOILS, THE HIDDEN KEY TO CLIMATE CHANGE ADAPTATION AND SDGS: CHALLENGES, THREATS, SUCCESS STORIES**

LEAD CONVENER:

M. FREPPAZ – University of Torino – DISAFA, Grugliasco, ITALY

CO-CONVENERS:

S. STANCHI – University of Torino – DISAFA, Grugliasco, ITALY

B. VRSCAJ – Agricultural Institute of Slovenia, Ljubljana, SLOVENIA

M. D'AMICO – University of Milano – Department of Agricultural and Environmental Sciences, Milan, ITALY

### **133530 - SOIL DEGRADATION CONTROL, REMEDIATION AND RECLAMATION**

**LEAD CONVENER:**

S. NORRA – Potsdam University, Potsdam , GERMANY

**CO-CONVENER:**

A. KARCZEWSKA – Wroclaw University of Environmental & Life Sciences, Wroclaw, POLAND

### **133539 - DEVELOPMENT OF EFFICIENT SOIL EDUCATION SCHEME FOR TOMORROW**

**LEAD CONVENER:**

T. KOSAKI – Aichi University, Nagoya, JAPAN

**CO-CONVENERS:**

K. MORI – Saitama Museum of Rivers, Yorii-Machi, JAPAN

C. ZACCONE – University of Verona, Verona, ITALY

T. SANDEN – Austrian Agency for Health and Food Safety, Vienna, AUSTRIA

### **133547 - LANDUSE CHANGE IMPACTS ON SOIL HEALTH**

**LEAD CONVENER:**

G. FENG – USDA-ARS, Genetics and Sustainable Agricultural Research Unit, Starkville, USA

**CO-CONVENERS:**

T.T. CHANG – Hohai University, College of Agricultural Science and Engineering, Nanjing, CHINA

Y.J. ZHANG – Hohai University, College of Agricultural Science and Engineering, Nanjing, CHINA

### **133566 - SOIL FAUNA AS A TOOL TO IMPROVE SOIL HEALTH ASSESSMENT**

**LEAD CONVENER:**

C. MENTA – University of Parma, Department of Chemistry, Life Sciences and Environmental Sustainability, Parma, ITALY

**CO-CONVENERS:**

G. PERES – Institut Agro Rennes-Angers, Département Milieu physique, paysage, territoire, Rennes, FRANCE

L. D'AVINO – Council for Agricultural Research and Economics, Research Centre for Agriculture and Environment, Firenze, ITALY

B. MANACHINI – University of Palermo, Department of Agricultural, Food and Forest Sciences, Palermo, ITALY

### **133568 - MANAGING SOIL CARBON AND NITROGEN FOR CLIMATE-SMART AND SUSTAINABLE AGRICULTURE**

LEAD CONVENER:

X. YAN – Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

CO-CONVENERS:

P. KIM – Gyeongsang National University, Jinju, SOUTH KOREA

S. CHANG – University of Alberta, Edmonton, CANADA

### **133569 - REVITALIZATION OF MINING RESIDUE DEPOSITS**

LEAD CONVENER:

A. KARCZEWSKA – Wrocław University of Environmental and Life Sciences, Inst. of Soil Science, Plant Nutrition and Environ. Protection, Wrocław, POLAND

CO-CONVENERS:

S. NORRA – University of Potsdam, Division of Soil Science and Geoecology, Potsdam, GERMANY

### **133571 - CONTAMINANTS OF EMERGING CONCERNS IN SOIL: OCCURRENCE, FATE AND TRANSPORT, TOXICITY AND REMEDIATION**

LEAD CONVENER:

Y. ZHU – Research Center for Ecoenvironmental Sciences, Chinese Academy of Sciences, Beijing, CHINA

CO-CONVENERS:

X. SONG – Nanjing Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

Y. LUO – Nanjing Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

H. LI – Department of Plant, Soil and Microbial Sciences, Michigan State University, East Lansing, USA

### **133576 - SOIL N<sub>2</sub>O EMISSIONS: UNDERSTANDING THE UNDERLYING MECHANISMS AND ASSESSING THE IMPACT OF SOIL MANAGEMENT STRATEGIES**

LEAD CONVENER:

E. DIAZ-PINES – University of Natural Resources and Life Sciences Vienna (BOKU), Institute of Soil Research, Vienna, AUSTRIA

CO-CONVENER:

A. LAGOMARSINO – Consiglio per la Ricerca in Agricoltura e l'analisi dell'economia agraria (CREA), Centro di Ricerca Agricoltura e Ambient, Impruneta, ITALY

### **133577 - SUSTAINABLE SOIL MANAGEMENT AND AGRONOMIC PRACTICES FOR CARBON FARMING: CHALLENGES AND OPPORTUNITIES**

**LEAD CONVENER:**

M. FRANCONI – Dipartimento di Scienze Agrarie, Alimentari ed Ambientali, Ancona, ITALY

**CO-CONVENERS:**

P.A. DELIGIOS – Dipartimento di Scienze Agrarie, Alimentari ed Ambientali, Ancona, ITALY

A.W. KISHIMOTO-MO – Institute for Agro-Environmental Sciences, National Agriculture and Food Research, Tsukuba, JAPAN

### **133578 - SOIL CARBON FARMING PRACTICES IN THE AGRICULTURE AND FORESTRY SECTORS**

**LEAD CONVENER:**

T. CHITI – University of Tuscia, Viterbo, ITALY

**CO-CONVENER:**

A. REY SIMO – Department of Biogeography and Global Change, National Museum of Natural Science (MNCN) Spanish Scientific Council (CSIC), Serrano, Madrid, SPAIN

### **133580 - SUSTAINABLE GRASSLAND MANAGEMENT FOR HEALTHY SOILS AND VICE VERSA**

**LEAD CONVENER:**

E. VÁZQUEZ – Departamento de Producción Agraria, Universidad Politécnica de Madrid, Madrid, SPAIN

**CO-CONVENERS:**

J. ARANGO – Tropical Forages Program, The Alliance of Bioversity International and CIAT, Cali, COLOMBIA

M. BENITO – Departamento de Producción Agraria, Universidad Politécnica de Madrid, Madrid, SPAIN

### **133583 - SOIL CARBON SEQUESTRATION AND LAND USE CHANGE**

**LEAD CONVENER:**

G. FENG – Genetics and Sustainable Agriculture Research Unit USDA-ARS, Starkville, USA

**CO-CONVENER:**

F. ZÚÑIGA – Universidad Austral de Chile, Instituto de Bosques y Sociedad, Valdivia, CHILE

### **133598 - ANTHROPOGENIC DRIVERS OF SOIL BIODIVERSITY, ITS FUNCTION AND FEEDBACK TO CHANGES**

**LEAD CONVENER:**

X. SUN – Institute of Urban Environment, Chinese Academy of Sciences, Xiamen, CHINA

**CO-CONVENERS:**

A. POTAPOV – German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Leipzig, GERMANY

Q. HAN – Integrated Research on Disaster Risk, Chinese Academy of Science (CAS), Beijing, CHINA

F. LIAN – Integrated Research on Disaster Risk, Chinese Academy of Science (CAS), Beijing, CHINA

### **133607 - BLACK SOILS: THEIR IMPORTANCE FOR FOOD SECURITY AND CARBON NEUTRALITY**

**LEAD CONVENER:**

Z. GANLIN – Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

**CO-CONVENERS:**

P. KRASILNIKOV – Moscow State University, Moscow , RUSSIA

M. TABOADA – USDA-Institute of Soil Science, Buenos Aire, ARGENTINA

### **133608 - DEVELOPING NEW MODELS OF URBAN SOILS**

**LEAD CONVENER:**

C. COLOMBO – Department Agriculture, Environment and Food Science, University of Molise, Campobasso, ITALY

**CO-CONVENERS:**

P.M. GROFFMAN – CUNY Advanced Science Research Center at the Graduate Center, New York, USA

Z. CHENG – CUNY Brooklyn College Department of Earth and Environmental Sciences, New York, USA

### **133609 - HOW WILL WE MONITOR SOILS IN THE COMING CENTURY?**

**LEAD CONVENER:**

A. BISPO – INRAE, Orleans, FRANCE

**CO-CONVENER:**

M. FANTAPPIE – CREA, Firenze, ITALY

### **133610 - CHARACTERIZING AND SELECTING SOIL HEALTH INDICATORS AT VARIOUS SCALES**

LEAD CONVENER:

I. COUSIN – INRAE, UR Info&Sols, Orléans, FRANCE

CO-CONVENERS:

C. CHENU – INRAE, UMR ECOSYS, Saclay, FRANCE

F. UNGARO – CNR, IBE, Firenze, ITALY

S. MOCALI – CREA, Firenze, ITALY

### **133611 - SOILS AND THE ENVIRONMENT**

LEAD CONVENER:

M. MUÑOZ ROJAS – University of Seville, Seville, SPAIN

CO-CONVENERS:

P. PEREIRA – Mykolas Romeris University, Vilnius, LITHUANIA

M.E. LUCAS-BORJA – University of Castilla La Mancha, Albacete, SPAIN

### **133622 - SOIL ORGANIC MATTER STABILITY AS KEY DRIVER TO SOIL CARBON SEQUESTRATION**

LEAD CONVENER:

L. MARTIN-NETO – Embrapa Instrumentation, São Carlos, BRAZIL

T. CHITI – University of Tuscia, Viterbo, ITALY

G. ZHANG – Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, CHINA

CO-CONVENERS:

D.P. DICK – Federal University of Rio Grande do Sul, Porto Alegre, BRAZIL

H. KNICKER – IRNAS-CSIC, Seville, SPAIN

### **133628 - MICRO- E NANOPLASTICS (MNPS) IN SOIL ECOSYSTEM**

LEAD CONVENER:

L.P. D'ACQUI – Italian National Research Council-Research Institute on Terrestrial Ecosystems (CNR-IRET), Sesto Fiorentino, ITALY

CO-CONVENERS:

S. DI LONARDO – Italian National Research Council-Research Institute on Terrestrial Ecosystems (CNR-IRET), Sesto Fiorentino, ITALY

O.L. PANTANI – University of Firenze, Firenze, ITALY

## **133791 - SOIL RESEARCH TOWARDS DISASTER RISK REDUCTION**

LEAD CONVENER:

F. LIAN- Integrated Research on Disaster Risk, Beijing, CHINA

CO-CONVENER:

F. TERRIBILE – Università di Napoli Federico II, Portici, ITALY

D. CALCATERRA – Università di Napoli Federico II, Napoli, ITALY

## **5. SOIL IN THE CIRCULAR ECONOMY**

### **133614 - SOIL NEEDS IN INDUSTRIAL AGRICULTURE AND HIGHLY POPULATED AREAS**

LEAD CONVENER:

M. CAGGIANO – Re Soil Foundation, Torino, ITALY

## **6. SOIL IN THE DIGITAL ERA**

### **125400 - APPLICATIONS OF PROXIMAL SOIL SENSING TECHNOLOGIES AND BEYOND**

LEAD CONVENER:

A. WADOUX – LISAH, Univ. Montpellier, IRD, INRAE, Institut Agro Montpellier, Montpellier, FRANCE

CO-CONVENER:

S. PRIORI – University of Tuscia, Department of Agriculture and Forest Sciences, Viterbo, ITALY

### **129252 - QUANTIFYING AND MAPPING SOIL FUNCTIONS**

LEAD CONVENER:

A. WADOUX – LISAH, Univ. Montpellier, IRD, INRAE, Institut Agro Montpellier, Montpellier, FRANCE

CO-CONVENER:

T. MULDER – Soil Geography and Landscape group, Wageningen University and Research, Wageningen, THE NETHERLANDS

## **129517 - DIGITAL SOIL MAPPING AND ASSESSMENT AT DIFFERENT SCALES – WHERE TO GO NEXT?**

LEAD CONVENER:

L.P. POGGIO – ISRIC – World Soil Information, Wageningen, THE NETHERLANDS

CO-CONVENERS:

J. HANNAM – Cranfield University, Cranfield, UNITED KINGDOM

M. NUSSBAUM – Berner Fachhochschule, Bern, SWITZERLAND

M. FANTAPPIÈ – Council for Agricultural Research and Agricultural Economy Analysis – CREA, Firenze, ITALY

## **129630 - SOIL AND VITICULTURE**

LEAD CONVENER:

A. BONFANTE – National Research Council of Italy (CNR-ISAFOM), Portici, ITALY

CO-CONVENER:

L. BRILLANTE – California State University Fresno, Fresno, USA

## **133437 - NOVEL APPROACHES TO PROCESS-BASED MODELLING IN AGRICULTURAL SOILS**

LEAD CONVENER:

M. VALADARES GALDOS – Rothamsted Research, Harpenden, UNITED KINGDOM

CO-CONVENER:

M.F. COTRUFO – Colorado State University, Fort Collins, USA

## **133441 - SOIL EROSION AND LAND DEGRADATION: METHODS, OBSERVATIONS AND PERSPECTIVES**

LEAD CONVENERS:

R. CIAMPALINI – Department of Earth Sciences / University of Florence, Florence, ITALY

D. GODONE – National Research Council Research Institute for Geo-Hydrological Protection, Turin Office, Turin, ITALY

CO-CONVENERS:

# IUSS PLENARY SPEAKERS

## OPENING SPEECH

### 100 YEARS OF SOIL SCIENCES

Edoardo A.C. Costantini

International Union of Soil Sciences, President

CNR-IBE, Sesto Fiorentino, 50019 (Italy)

Reporting facts is no longer enough. To really engage laypeople and stakeholders we have to tell a story, and we have a great story to share.

One hundred years ago, on the 19th of May, our Society was established in Rome during the Fourth International Conference of Pedology. For one hundred years, our organization has served as the home for soil scientists from all corners of the globe. The main global melting pot of Soil Sciences, where new ideas are forged and tested by peers.

The inauguration speech of the Centennial Celebration and Congress delineates the distinctive traits of the International Union of Soil Sciences, illustrating the organization's nature and operational framework, including its composition, governance, and scientific structures.

The innovative approach employed to organize the event, based on a bottom-up methodology, is explained, highlighting the key components of the program. The themes of the Congress are not only centred around Science but also encompass Knowledge, drawing from lessons learned in our history and acknowledging that our future is rooted in the past.

Special emphasis is placed on valuing insights from colleagues in other disciplines, including social sciences, education, humanities, and art, who deliver remarkable presentations and exhibitions during the Congress, and a thematic excursion. This holistic approach ensures a comprehensive exploration of Soil Sciences and their broader implications.

**Key words:** IUSS, Centennial, Celebration, Congress, inauguration speech.

### EARLY INTERNATIONAL CONNECTIONS IN THE DEVELOPMENT OF SOIL SCIENCE

ALFRED HARTEMINK

The University of Wisconsin-Madison, Department of Soil Science, FD Hole Soils Lab,  
1525 Observatory Drive, Madison 53711, USA

The scientific study of soil became more systematic and profound when researchers from different countries started to visit each other's laboratories. Findings and ideas were exchanged on how plant take up nutrients, how soils were formed, and how to measure the texture of the soil. Some had a background in agricultural chemistry, others were schooled in geology or bacteriology. The *International Society of Soil Science* was formed to accelerate the exchange of information, to develop a common language, and to standardize procedures for soil analysis and classification. The *Fourth International Conference of Pedology* was held in Rome in 1924 and brought together 300 soil researchers. A large group of soil scientists gathered at the *First International Congress of Soil Science* that was held in the USA in 1927 and included an extensive fieldtrip across the USA and Canada. It created a soil community and format that was used in subsequent soil congresses that were held across the globe. In this talk, I will review some of the great international connections and scientific explorations which were vital for the development of soil science.

### DIVISION 1

#### THE EVOLUTION OF PEDOLOGY - DRAWING FROM THE PAST, ADAPTING TO THE FUTURE

ALEX. MCBRATNEY

The University of Sydney, AUSTRALIA

Pedology – the fundamental understanding of soil in space and time has been studied effectively and energetically for more than a century. What is its future? There are many possibilities; here are three areas which, if attended to, will pay dividends for pedology.

- 1) Pedology has been cautious generally in taking up new technologies and ideas; while some areas have moved forward profitably. It is beyond doubt that pedology can be aided by the digital age. To some degree all of our research and teaching had been enabled, enhanced and expanded by digital convergence. Digital proximal and remote soil sensors have been widely implemented, and new tools such as cell phones and apps, and metagenomics techniques are becoming available. There are areas crucial to pedology for which no major digital technology obstacles exist, but which have not been thoroughly investigated, e.g. to devise a truly digital soil field description or the building of a formal digital quantitative system of soil identification and classification. There are some caveats brought by digital convergence such as the lack of new theory, proprietary (black-box) soil prediction and lack of new understanding brought by machine-learning models. A future of what may lie over the horizon of digital pedology soil science is prognosticated.
- 2) The realisation, that *h* humanity is fast becoming the most important soil-forming factor requires us to change our thinking substantially. For example, the increase in temperature of soil profiles by at least 1C degree to depth all over the world, through human-induced climate change, will alter properties and increase the rate of soil processes everywhere.
- 3) Finally, soil is key to existence. Rather than downplaying the pedocentric view we should advocate soil centrism with vigour and enthusiasm. Such a view is lead by pedology.

### DIVISION 2

#### SOIL PROPERTIES AND PROCESSES - RETHINKING THE TRANSFORMATIVE POWER OF SOIL

GEORG GUGGENBERGER AND JENS BOY

Leibniz University Hannover, Institute of Earth System Sciences, Section Soil Science, GERMANY

Climate change, overutilization of natural resources and demographic changes are just a few pressures on our societies we caused by transforming nature without foreseeing the outcome. Nowadays we are increasingly able and willing to understand transformative power of nature, even in its most complex ecosystem compartment - the soil. Thus, we need to learn from the transformative power of soil, foster this power and use it to cope with the above-mentioned challenges by this.

Sustainable and regenerative agriculture is based on less energy and nutrient input to assure a high and stable yield without harming or even improving the environment. This requires the transformative power of soil with respect to the reestablishment of plant-microbiota-soil interactions. Functional diversity in soil can be used as a key transforming agent in agriculture and ecosystem conservation. Tight and diverse plant-microbiota-soil interactions at microinterfaces are prerequisites for closing nutrient cycles, re-establishing a good soil structure, controlling pests, and thus assuring food security. At the end soil and its organisms can be even used in industrial processes like the production of biotic concrete.

We just need to unleash and foster the soil's transformative power for the good of our environment and our societies.

### DIVISION 3

#### FROM SUMERIAN AGRICULTURE TO THE AGRICULTURE OF THE 3RD MILLENIUM: SOIL SALINIZATION, A WORLDWIDE CONCERN. THE ROLE OF IUSS COMMISSION 3.6.

JORGE BATLLE-SALES

IUSS Commission Chair and INSAS Chair, Murcia, SPAIN

Soil salinization, characterized by the accumulation of salts in soil, has been a historical concern, with roots tracing back to ancient civilizations like the Sumerians around 4000 BCE. The Sumerians, pioneers of irrigation agriculture, inadvertently triggered soil salinization through the buildup of salts from irrigation water from Euphrates and Tigris, which contributed to the decline of their civilization.

Today, the challenges of soil salinization are compounded by global warming and climate change, exacerbating aridity in many regions worldwide. Areas already susceptible to aridity face intensified water stress, further complicated by the imperative to sustain a growing global population.

The issues surrounding salt-affected soils have garnered widespread international interest among soil scientists for decades. Even before the establishment of the International Society of Soil Science (ISSS) in 1924, concerns about salt degradation prompted the formation of specialized groups. The Alkali Subcommittee, established during the 1st International Congress of Soil Science in 1927, was the pioneering effort within the ISSS to address this issue.

Over time, the focus of soil conservation has evolved in response to changing societal paradigms. Initiatives initially aimed at expanding irrigated agriculture by reclaiming wetlands gradually shifted towards conservation movements emphasizing resilience and sustainability in natural and agricultural ecosystems. Presently, the conservation paradigm has progressed towards ecosystem restoration, exemplified by recent legislative efforts such as the EU's commitment to restoring 20% of degraded ecosystems by 2030.

In 2019, the International Network on Salt-Affected Soils was launched under the auspices of the FAO-Global Soil Partnership. This initiative efforts, concretized in organized symposia, publications, webinars, and working groups activity, aligns synergistically with the efforts of the Commission on Salt-Affected Soils of the International Union of Soil Sciences (IUSS). The forthcoming Global Status of Salt-Affected Soils report, compiled by the INSAS, promises to serve as a comprehensive reference document for scientists, technicians, farmers, and stakeholders alike, fostering informed action towards addressing the challenges posed by soil salinization in the modern era.

### DIVISION 4

#### THE ROLE OF SOILS IN SUSTAINING SOCIETY AND THE ENVIRONMENT: A CARBON MANIA?

Claire Chenu

INRAE, France

In the last ten years, soil carbon has received a great deal of attention from the research community and receives much attention from the media and society at large, both from a climate and from a soil health perspective. Here, we ask whether it is a real trend, whether it is justified and what are the characteristics and outcomes of this trend.

Indeed, the proportion of soils-related scientific articles devoted to soil carbon has increased over the last decades. The attention given to soil carbon is sustained by the fact that soil organic matter is key to soil functions and ecosystem services, and is highly responsive to ecosystem management. Furthermore, the large size of the soil carbon pool has brought soils into the debates on global change and climate change mitigation.

This has led to, or been associated with, a rapid knowledge development about the nature and dynamics of soil organic matter and paradigms have changed. The centrality of soil organic matter relative to soil function, and that soil carbon has long been measured, makes it the soil characteristic most widely measured soil characteristic in soil monitoring. However, measurement methods are still not harmonized and the soil carbon targets and thresholds needed to assess soil health have not yet been defined.

In terms of knowledge sharing and transfer, soil C has been an effective communication tool over the last decade, but is associated with oversimplification, as soil organic matter is not just carbon.

In terms of knowledge application, soil carbon management is a powerful lever for protecting or restoring soil health. The idea that there is no silver bullet in terms of management of agricultural soils and that sustainable soil management is specific to the pedoclimatic context seems to have made good progress, but still lacks developments on the ground. In the policy arena, soil carbon is at the heart of global initiatives, such as the 4p1000 initiative and has been taken up by EU and international policies, as a multifaceted indicator.

Overall, we discuss whether developing, sharing and transferring, harmonizing and organizing as well as applying knowledge on soils has benefited from soil carbon being used as a banner.

### THE ROLE OF SOIL IN THE GLOBAL POLICIES

SALVATORE ARICÒ

CEO, International Science Council, Parigi, FRANCE

The recognition of soil diversity and the importance they play in ensuring ecosystem services – from provisioning to cultural – has been consolidated in the past 20+ years largely due to relevant policy processes at the global level. What scientists have advocated in scientific terms for more than a century has come to policy and wider public acceptance also in light of pressing societal issues such as food insecurity including famine, human and environmental health concerns, poverty and inequality, as well as the expansion of global markets and how these impinge on food commodities and the underpinning soil properties and management, etc. In such a context, soil sciences often had to provide responses to societal concerns more promptly than other branches of sciences. In doing so, soil scientists possibly learned from the crises it faced more learned than other branches of science and, today, they have adapted, evolved and are now increasingly capable of providing anticipatory insights into how soils should be managed, governed and protected for the safety and security of society. This plenary lecture will illustrate how soil sciences have responded to solicitations beyond conventional research questions and learned to put inter- and increasingly trans-disciplinary sciences and knowledge in action. The International Union of Soil Sciences is quite fit-ready to tackle these and further upcoming challenges, and the International Science Council, of which the IUSS is a member, stands ready to continue accompanying and working with the IUSS in its role of delivering actionable knowledge on soil issues for the benefits of society.

### **PROTECTING SOILS FOR FUTURE GENERATIONS: THE DEVELOPMENT OF SOIL POLICIES IN EUROPE AND IN THE WORLD**

LUCA MONTANARELLA

Chair - International Network of Soil Information Institutions (INSII) of the GSP, Ispra, VA, ITALY

Soil can be considered as a non-renewable natural resource, given the long time frame needed for its formation. Hence the need for sustainable management in order to assure that this precious limited resource will be available also for future generations. There is the need to develop appropriate policy instruments creating the necessary legal framework for the implementation of sustainable soil management practices. Unlike air and water, soil related policies need to be locally tailored to the very different pedoclimatic conditions. Soils are highly variable in their properties in space while being relatively resilient in time. In Europe the European Union has been at the forefront of the development of transnational soil policies aiming at the achievement of sustainable soil management. Starting from 2006 several legislative proposals have been put forward by the European Commission addressing sustainable soil management. At global scale, following the adoption of the World Soil Charter, the development of the Global Soil Partnership has been driving the establishment and implementation of many programs and initiatives that have raised awareness of the relevance of protecting soils for food security and sustainable development.

### **SOIL HEALTH TOWARDS THE REALIZATION OF SUSTAINABLE DEVELOPMENT GOALS: PROGRESS AND TRENDS IN CHINA**

XIN SONG, JIABAO ZHANG, RENFANG SHEN, ZHONGJUN JIA, HAIYAN CHU, RONGJIANG YAO

Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

Soil health is critical to human and planetary health and for achieving sustainable development goals (SDGs). In this study, the progress and trends of soil sciences in China towards the realization of zero hunger, human health, biodiversity and climate control are provided. We begin with the soil health assessment, in which a comprehensive set of indicators are developed, and a framework has been proposed. To achieve food security in China, research activities on sustainable plant production, including increasing soil productivity and reducing threats from soil acidification and soil salinization, are summarized. In the effort to reduce biodiversity loss, models with the functions of capturing and predicting spatial and temporal trends have been developed to track and conserve soil biodiversity. Furthermore, to meet China's share of greenhouse gas (GHG) emissions reduction in achieving carbon neutrality goals, the research progress on soil carbon sequestration and GHG emission reduction will be reported. Finally, an in-depth discussion on the soil pollution, in particular related to the emerging contaminants of per- and polyfluoroalkyl substances (PFASs), are presented. It is worth noting that the research activities on soil health in China focus on both technology development and implementation, such that these technologies remain relevant to all stakeholders.

### WHO CONSTITUTES THE FUTURE OF SOIL SCIENCES? – GENDER, AGE, AND CITIZENSHIP AMONG THE YOUNG AND EARLY CAREER SCIENTISTS

AXEL CERÓN GONZÁLEZ<sup>1,2</sup> AND BARTŁOMIEJ GLINA<sup>1,3</sup>

<sup>1</sup> International Union of Soil Sciences “Young and Early Career” Working Group

<sup>2</sup> Vrije Universiteit Brussel, Belgium

<sup>3</sup> Poznań University of Life Sciences, Poland

The *International Union of Soil Sciences* (IUSS) witnesses a century-long narrative of technological and social transformations, significantly influencing the path of individuals becoming soil scientists. Although the IUSS has been essential in diversifying soil paradigms since the 1920s, the last decade condensed a disrupting episode to amend structural disparities among soil scholars. The democratic election of the first woman from the Global South as IUSS President in 2018 and the establishment of the Young and Early Career Working Group (YECS) in 2022 represent a shift towards considering three components in shaping the future of soil sciences —gender, age, and citizenship.

Who constitutes the future of soil sciences? An exploration into the fabric of YECS, featuring over 350 members from 58 countries who responded to a structured questionnaire as of January 2024, reveals intriguing singularities. Europe is nearing gender equity, and Latin America demonstrates increased participation of young women. The average age of young soil scientists worldwide is 30 years. Notably, there are distinct gender variations in the Middle East, where the average age for men is 27 years, while for women is 35 years. Similar patterns persist within IUSS, women are prominently engaged in *Division 4 – Sustaining Society and the Environment*, while men continue to lead the rest. Analysis of binary gender and age disparities among young soil scientists reveals potential areas for improvement within YECS and IUSS. This prompts reflection on strategies to promote more diverse spaces, including potentially underrepresented queer identities. For a more inclusive future soil science.

**Keywords:** soil science paradigms, structural disparities, diversity, inclusive future

**FROM TRADITIONAL KNOWLEDGE TO SCIENTIFIC UNDERSTANDING: EMPOWERING RURAL WOMEN TO PROMOTE SOIL HEALTH IN THE CONGOLESE COASTAL PLAINS**

L.S. KOUTIKA

CRDPI, Pointe-Noire, REPUBLIC OF THE CONGO, CONGO (BRAZZAVILLE)

For centuries, rural population of the Congolese coastal plains used to be very mobile following numerous epidemics, conflicts with another ethnic group and/or crop yield decline. These three main drivers of this mobile life style led to the permanent search for the healthy and peaceful land and potential increased crop production. This mobile life style helped to restore the health and biodiversity of soil and ecosystem. However, the slash-and-burn, a common and widely used practice in the tropics, mainly in Sub-Saharan Africa (SSA) including the Congolese coastal plains, harms soil land and ecosystems. The practice deteriorates soil health i.e., the decline in biological activity and organic residues, quick release of nutrients, and reduced physical properties (aggregation, porosity).

For over five decades, research has been conducted in silviculture, environment and socio-economic for surrounding population of forest plantation ecosystems established in the Congolese coastal plains. It highlighted how the health of nutrient-poor and sandy soil could be improved through organic matter management or introduction of nitrogen-fixing species (NFS). Mixed-species plantations involving NFS improved C and N stocks, and available P, i.e., soil health. Non-fixing species benefit from N<sub>2</sub> fixed by NFS, while stand wood biomass increased in mixed-species stands relative to monoculture of both NFS and non-NFS. This warrants the need of population in fuel wood energy as over 90% of households rely on fuel wood energy.

The transfer of these findings to societies, through participatory research i.e., project implementation is barely made in the Congolese coastal plains, regardless of tremendous scientific findings. Congolese society and especially rural populations have very limited knowledge of these findings. A project on agroforestry systems aiming to empower rural women through C capture to mitigate climate change, boost soil fertility and staple food security in the Congolese coastal plains has been implemented. Funded by TWAS-UNESCO and ELSEVIER Foundation, this project is promoting the transfer of scientific knowledge, while considering positive aspects of traditional knowledge.

### 2. Soil and humanity

#### 2.01 124495 - Youth digging - The progress of early career global soil research

##### UNVEILING YOUTH INVOLVEMENT IN SOIL RESEARCH, EDUCATION, AND AWARENESS IN A RESOURCE CONSTRAINED ENVIRONMENT

R.B. OJHA, D. DEVKOTA

Nepal Agricultural Research Council, LALITPUR, NEPAL

Acknowledging the fact that there is a deficit of human resources in soil education and research worldwide, the South Asian context is not an objection amidst resource constraints. This study is a nationwide survey and a personal experience shared by an early-career scientist from Nepal, a resource-constrained country in South Asia. In Nepal, seven universities (private and public) offer undergraduate soil courses and two universities offer postgraduate soil courses. Annually, around 20 postgraduates enter the job market. This survey aims to understand the retention and motivation of young soil graduates in the national soil research, education, and extension sectors under resource constraints. Soil research and extension depend on soil education, but our preliminary findings suggest that the disconnection between education and research/extension leads to the incapacity of human resources in research and extension, resulting in poor development of soil technologies and inadequate extension/awareness. Moreover, the lack of human resources (60% deficiency in research and 40% deficiency in extension), limited financial resources (<0.01% research budget), and few capacity development programs (<5 trainings) worsen the situation. Therefore, it is a major concern that requires global attention to encourage and support youths from the developing world to work in resource-constrained environments and to enhance capacity development and research funding.

#### A CENTURY OF SOIL SCIENCE EVOLUTION DOCUMENTED IN THE NATURE AND PROPERTIES OF SOILS TEXTBOOK

R. WEIL

University of Maryland, Dept. of Environmental Science and Technology, College Park, USA  
RAYRWEIL SOILSCIENCE, Hyattsville, USA

The Nature And Properties of Soils has served as an introductory University soil science textbook as well as a professional reference for more than 100 years. First published in 1922 under the authorship of TL Lyon and H O Buckman, the book was an outgrowth of an earlier book first published in 1905 under the title Soils their Properties and Management at Cornell University in the US state of New York. Generations of soil scientists throughout the world have been educated using later editions of this textbook, which has been translated into many of the world's major languages. The evolution of this textbook reflects the evolution of both the science of soils and the pedagogy of University teaching. This talk will highlight how basic concepts of soil science from pedology to soil physics, from soil chemistry to soil ecology have changed over the past century. In some cases, classic concepts have stood the test of time while in other cases they have been refuted and replaced with more modern and accurate approaches.

Even in this digital age, the textbook plays an important role in both education and knowledge consolidation and integration. This textbook provides an integrated systems view of soils that fragmented Google searches and multi-author chapter compendiums cannot replace. With modern teaching approaches using a “flipped classroom” in which students spend in-class time with the professor solving problems while preparing themselves with out-of-class learning, the role of the textbook may even have increased its importance compared to earlier generations.

### 2. Soil and humanity 2.03 129617 - Soil Health from Multiple Perspectives

TODAY'S ECOLOGICAL ARTISTS ENGAGING SOILS AS BOTH MEDIUM AND NON-HUMAN COLLABORATOR

P. WATTS

Ecoartspace, Santa Fe, USA

Iron and other minerals found in soils have provided a range of pigments for making paintings dating back over 45,000 years. The oldest is a recently discovered drawing made with red ochre pigment found in a limestone cave in Indonesia. In the late 1960s, contemporary artists began a new relationship with soils, reaching beyond the material resource to depict representational art. Art movements that evolved along with the genre of Conceptual Art included the Arte Povera movement in Italy and the Earth Art movement in the United States. A radical notion of what art could be emerged for artists working with unprocessed materials and while creating art outdoors in and with nature. This was a distinct reaction to emergent consumer culture, where art was being made to blur with everyday life. In 2021, the international ecological art platform ecoartspace initiated the Soil Dialogues for artists and scientists interested in soils and textiles to collaborate on a project. The common focus has been the technique of burying decomposable textiles in soil to visualize soil chemical and microbial activity. Approximately thirty artists have met monthly via Zoom for almost three years to discuss their unique sites. Some artists did soil nutrient testing and soil DNA extraction to learn more about the microbiological profile of each site. After the artists' unearthing of the textiles, they observe and document the soil interactions and then decide how they will co-create their unique soil story. The interpretation of the range of colors and other evidence of microbial activity is unique to each artist. Other artists will add additional media to the textile, performing a collaborative artwork with the non-human world. For my presentation, I will share examples of early soil care art practitioners and the outcomes from the Soil Dialogues including the artists' process, and their research findings; providing an arts and cultural perspective for inspiration and dialogue around soil health with a broader audience.

##### NURTURING SOIL LITERACY: THE INNOVATIVE STRATEGIES FOR AWARENESS AND ACTION OF FAO'S GLOBAL SOIL PARTNERSHIP

I. VERBEKE, C. HUMURA, M. FURENTI

FAO - Food and Agriculture Organization of the United Nations, Global Soil Partnership of the Land and Water Division, Rome, ITALY

Established in December 2012, the Global Soil Partnership (GSP) of the Food and Agriculture Organization of the United Nations (FAO) serves as a globally recognized mechanism with the mission of elevating soils in the global agenda and advocating for sustainable soil management. As part of its mission, it also seeks to raise awareness on the vital role of soils in promoting healthy populations and ecosystems, thus reducing soil illiteracy through effective communication strategies.

World Soil Day, celebrated every year on 5 December, is a platform dedicated to preserving soil health and promoting sustainable soil management to a wide audience. With this in mind, the GSP, together with all FAO Members, has launched impactful activities such as the King Bhumibol World Soil Day Prize and the Glinka World Soil Prize to bring soil research and innovation into people's daily lives. Through these awards, outstanding organizers and field-oriented work are recognized, strengthening society's awareness of the essential role and value of soil.

The GSP reinforces soil education with interactive materials, including activity books and laboratory experiments for children. Painting competitions for children and teenagers, combined with tutorials on soil painting techniques, promote hands-on learning about the importance of soil in everyday life.

Numerous competitions and activities, such as 'From soil to plate', child-oriented laboratory experiments and annual photo, book and poster contests, have involved citizens of all ages by highlighting the societal importance of soil.

Throughout the year, the GSP, with the support of FAO's corporate communications unit, actively engages with a global, diverse audience on various social media on soil health and protection encouraging all to take action. Through this range of activities, the strategy has successfully mobilized billions of people, sparking collective imagination and connecting with citizens' lives with the overall objective to contribute to the green transition by promoting soil health and sustainability. This approach surpasses the mere provision of scientific information, resonating with people's existing practices, values, and concerns.

**NEW APPROACHES TO SOIL AND WATER MANAGEMENT AND CONSERVATION FOR A SUSTAINABLE FOOD PRODUCTION UNDER FUTURE GLOBAL CHANGES**

ILDEFONSO PLA

Universitat de Lleida, Leida, Spain

Soil and Water resources are the basis for current and future food production and water supply for an increasing population and plays a central role in determining the quality of our environment. Both resources are subjected to increasing pressure under global change effects, including population growth, land use and management and global climate changes. Water resources management and land management are intricately linked. Increasing competing demands will reduce land and water availability for food production. At the same time, expected increases in food demands will require increased agricultural production and agricultural water use. Increased human influences on soils frequently results in widespread land and soil degradation processes. Associated with land and soil degradation there is a decrease in available and acceptable quality water for agriculture, urban and industrial needs, and decreased biodiversity. The of soil and water degradation processes are linked through unfavorable alterations of the hydrological processes determining soil water regimes. Like climate, soil and socio-economic conditions differ significantly from one location to another, and because they are changing continuously, there cannot be simple universal prescriptions about practices for sustainable soil management for crop production and environmental protection. A hydrological approach to the evaluation and prediction of the conservation of soil and water is essential for adequate development, selection and application of sustainable and effective land use and management practices. Based on that premise, we have derived a hydrological modeling approach, which may be and has been used to evaluate and predict soil hydrological processes and derived effects. Such a modeling approach can be adapted to deduce the appropriate land management for a more efficient and sustainable use of soil and water resources. The substantial number of factors, and their complex interactions, determining and affecting soil and water degradation processes, and conservation practices, require more interdisciplinary approaches and research, to be able to identify, to evaluate and to find adequate valid and sustainable alternatives to the different problems. The main objective

<sup>4</sup> Botanical Garden, University of Siena, Siena, ITALY

<sup>5</sup> CREA-AA council for agricultural research and economics, Agriculture and Environment, Firenze, ITALY

Increasing soil literacy in society is a current long-term objective of the European Union. The proliferation of soil museums in recent years is a step towards making soil as a cultural heritage. Similarly, bringing closer the soil to society comes through teaching, which requires basic knowledge about the soil system. In addition, the involvement of some artistic skills in the whole process could enhance the acquisition of fundamental concepts about the soil, which could derive into a sort of “soil art” practice. We aim to review some significant experiences in the representation of soil for educational and cultural purposes in Italy, which we call Terrae Scientia. This generic definition includes a whole series of exhibitions on soil that combine art and science. Some of them have been collected from the literature, while others come from our own experience and so, new terminology has been assigned to them (i.e. Soilfloor map). We summarized and evaluated the impact of each type of Terrae Scientia using a set of metadata that defines aspects such as the possible installation costs, purposes and benefits for educational learning, entertainment, and scientific and artistic value. We focus on those Terrae Scientia that, because of their interdisciplinary nature, are more closely linked to the territory, such as eco-museums. We found that soil monoliths are the most common form of illustrating soil in exhibitions, but other performances related to soil can be an alternative but equally impressive, and with a high educational value (i.e. pedolites or soilboxes). Special mention deserves the natural environment with presence of “pedosites”. They represent the best opportunity to organize natural itineraries that can be combined with teaching or rural tourism. We believe that the set of activities we collected improves soil culture to citizens of all ages, delivering an educational message through beauty and creativity. In addition, they could provide important employment opportunities for tour guides, exhibition curators, artists, information technology companies and freelancers.

**NOTES ON THE DEVELOPMENT OF A METHODOLOGY FOR SEMIQUANTITATIVE ASSESSMENT OF URBAN SOIL HEALTH**

R. PARADELO NÚÑEZ

Universidade de Santiago de Compostela, Santiago de Compostela, SPAIN

Soil health assessment is an essential part of policies for soil and environmental management and protection. In particular, maintaining and enhancing soil health can be particularly challenging in urban environments, where soils are exposed to many degradation processes and can be deeply disturbed by anthropic activities and contamination. However, many difficulties arise for the actual assessment of soil health and we are currently far from having widely accepted methods for assessment or even indicator selection. In this work, the development of a simple semiquantitative methodology for urban soil health assessment will be presented, based on scoring tables and the EU framework. The methodology has been tested using a database from previous works on the urban soils of Santiago de Compostela, including physical, chemical and biological properties in soils developed over different parent materials and under different land uses. Lessons learnt in this case study regarding the future development and application of soil health assessment schemes in urban soils will also be discussed.

**PLANT COVER AS AN IMPORTANT SOIL-FORMING FACTOR CONTROLLING TECHNOSOL EVOLUTION: A CASE STUDY FROM ABANDONED IRON ORE MINE IN POLAND**

L. UZAROWICZ<sup>1</sup>, W. KWASOWSKI<sup>1</sup>, J. LASOTA<sup>2</sup>, E. BLONSKA<sup>2</sup>, B. GÓRKA-KOSTRUBIEC<sup>3</sup>, M. TARNAWCZYK<sup>1</sup>, E. PAWLOWICZ<sup>1</sup>, D. MURACH<sup>1</sup>

<sup>1</sup> Warsaw University of Life Sciences - SGGW, Warsaw, POLAND

<sup>2</sup> University of Agriculture in Krakow, Krakow, POLAND

<sup>3</sup> Institute of Geophysics, Polish Academy of Sciences, Warsaw, POLAND

The objective of the study was to examine the transformations of properties of Technosols following spontaneous development of forest habitats on dumps of the former Fe ore mine in Czarniecka Góra village, S Poland. Despite the similar age (60 years), the soils showed differences in chemical and biological properties, which was related to the different degree of development of the plant cover appearing on the heap as a result of natural succession. The emergence of vegetation and its further development into more and more developed plant communities causes acidification of the upper part of the soil profile, washing out of carbonates from the upper parts of the soil and the accumulation of soil organic matter manifested by an increase in the content of TOC, TN in the upper parts of the soil. The highest magnetic susceptibility was found in the upper parts of the soil profiles representing the places with the most advanced succession. This suggests that the progress of pedogenesis on the studied heap probably causes the transformation of mineral phases towards phases with higher magnetic susceptibility. Development of vegetation on the heap promotes the development of microorganisms in Technosols, which is manifested by an increase in the enzymatic activity of soils in the upper parts of the profiles. The conducted research shows that plant cover is one of the most important soil-forming factors controlling the direction of property transformation of technogenic soil substrate and the course of soil-forming processes in the initial Technosols on post-industrial waste heaps.

OUR MOST USED SOILS ARE SUITMAS: THE CASE OF TRAFFIC SOILS IN URBAN AREAS

W. BURGHARDT

University Duisburg-Essen, Faculty of Biology, Essen, GERMANY

Why traffic soils? When thinking of soils, we have natural bodies in mind which developed by the action of their environment and by use. With coming up of civilization, and by this growing influence of men on environment, new ways of soil formation occur. They are based on men decisions and not on nature as factors of soil formation in landscapes. Thus we can discern two types of soil groups: Soils which are by-products and soils which are tied on the target of human activities. From many decisions of social affairs and economy follow as by-products movement, transport and deposition of soil and soil forming materials at diverse locations. The second type are soils such as of waste tips and of traffic areas which are bound to the intention of decisions and to defined locations.

Traffic soils are today the most used soils. Our fast growing urban areas would not be sustainable without traffic soils. Thus they provide a large part of SUITMAs (Soils of Urban, Industrial, Traffic, Mining and Military Areas). Traffic soils are soils of roads, paved walkways and gravel roads, and soils of train tracks. Soils of roads and paved walk ways are already known as Ekranosol and Dialeimmasol, and of train tracks as Intrusol. Until now, not described are gravel roads, which can be designated as Podosol (podo, greek foot). Like natural soils, traffic soils are subject of change by the impact of the environment.

This presentation will in short feature the development of traffic soils. The subsoil can vary according to the origin of the soil forming substrate, the site use and contamination. The top soil horizons correspond with the specific construction demands. There occur soil forming processes underneath the bearing layer and within the bearing layers from reduction, leaching and dust intrusion and dust deposition. Thus the individual traffic soils can be characterised by both: specific substrates (soil forming materials) und soil horizons.

#### ATMOSPHERIC DEPOSITION OF METALLURGICAL PARTICLES IN URBAN SOILS: HOW TO DETECT THEM AND MONITOR THEIR IN-SITU EVOLUTION AND MIGRATION ?

M. CASSETTA<sup>1</sup>, D. PRÊT<sup>2</sup>, L. COURCOT<sup>1</sup>, S. PHILIPPE<sup>1</sup>, C. LAFOREST<sup>2</sup>, M. HERMOSO<sup>1</sup>, J. CAILLAUD<sup>1</sup>

<sup>1</sup> Laboratoire d'Océanologie et de Géosciences - UMR 8187 - INSU, ULCO, U. Lille, CNRS, Wimereux, FRANCE

<sup>2</sup> Institut de Chimie des Milieux et Matériaux de Poitiers - U. Poitiers, INSU, CNRS, Poitiers, FRANCE

The atmosphere of Dunkerque agglomeration (northern France) is closely monitored due to the huge quantities of dust emitted by its metallurgical industries (> 2700t in 2021). In such a context, the atmospheric deposition of industrial metallic particles on the local soils is particularly pronounced. The fate of industrial metals in these ecosystems is a major concern, especially because of their potentially harmful effects on human health.

The city of Gravelines (Dunkerque agglomeration) is known to be exposed to chronic industrial dust fallout (particle size > 20 µm), especially during North-East windy and dry events. Anthropogenic particles such as coal, alumina dust, slag, iron ores... are thus incorporated into the soils. Each type of particle is identified by significant concentrations of specific metals (Cr, Ni, Mo...), enabling its environmental traceability.

Although total chemical analyses of topsoil samples collected in Gravelines showed diffuse metal contamination, their quality appears diminished by industrial metals according to Tomlinson et al. (1980) (PLI values ranging from 1.2 to 1.8). Besides, the fate of dust particles and their associated metals in soils remains of a significant interest in the long-term.

To understand the various processes involved in the integration of industrial dust in soils, large thick sections were made from contaminated soil cores (0-15cm) by using an advanced resin impregnation procedure. Scanning Electron Microscopy (MEB-FEG JEOL 7900F) coupled with cutting-edge annular EDS allowed (through high resolution, large field chemical mapping and image processing) to locate and identify in-situ atmospheric particles. In one soil section, more than 30 particles/cm<sup>2</sup> were counted in the first few centimeters. The coupling with µXRF analyses and mapping of trace elements (Cr, Ni, Mo...) makes it possible to precisely spatialize the industrial particles at core scale according to their tracer metals. This innovative approach enables to study the distribution of metallurgical particles within the soil and then to highlight their possible migration mechanisms and interactions with the different soil or biosphere components.

### 3. Soil governance

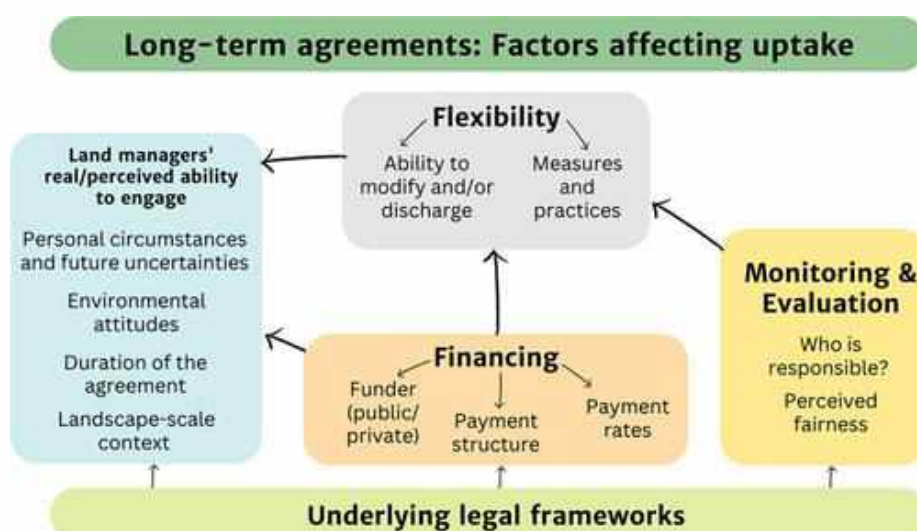

#### 3.08 133775 - Soil governance: building on stake-holders interactions and involvement for a sustainable management of soils

##### A CO-DESIGNED APPROACH TOWARDS DEVELOPING AN AGRI-ENVIRONMENTAL SCHEME WITH STAKEHOLDERS: LONG-TERM AGREEMENTS FOR LANDSCAPE-SCALE NATURE RECOVERY

C. CHIVERS, L. BARKELEY, C. SHORT

Countryside and Community Research Institute, University of Gloucestershire, Cheltenham, UNITED KINGDOM

Research was undertaken to explore the potential of long-term agreements (30 years+) for securing landscape-scale nature recovery in the UK. Improving soil health is paramount for achieving this goal, including ambitious measures such as land use change and the restoration of natural waterways. Measures and practices relevant to soil health were thus expected to be embedded throughout such agreements. A co-design research approach was used to iteratively engage with stakeholders, including agricultural land managers who would hold long-term agreements, alongside other interested parties who may be otherwise involved, for example through contributing to funding, monitoring, or evaluation. These stakeholders included representatives from various non-governmental bodies, private water companies, natural capital enterprises, and local nature partnerships. Here, we present the results of this research. A template long-term agreement was co-developed with stakeholders, where their views shaped both the research design and the outputs. A initial rapid evidence assessment, a series of workshops, interviews, and a public consultative webinar resulted in participants feeling empowered and feeling that the outputs which resulted reflected the views of all stakeholders, even those with differing agendas. The resulting template agreement was positively received despite continued uncertainties around the feasibility of long-term agreements themselves, largely because it was redrafted across the study, including after the final evaluation interviews and consultative public webinar. During this talk, we will share our co-design approach to governance and provide an overview of the resulting agreement template. Our approach, where stakeholders were repeatedly consulted with using a participatory methods, provides a useful approach for future democratically-focused stakeholder engagement relating to soil policy.

### 4. Soil health in achieving the Sustainable Development Goals 4.01 123826 - Soil science lessons from 100 years or more old experiments

#### LONG -TERM MANURE APPLICATION IMPROVES SOIL HEALTH IN CONTINUOUS MAIZE PRODUCTION SYSTEM

B MAHARJAN

University of Nebraska-Lincoln, Lincoln, USA

#### **Body**

Soil health lies at the core of a sustainable food production system. A comprehensive evaluation of different agronomic practices and their effect on soil health is essential to determine the best practices that support soil ecosystem services. However, it may take years or decades to observe measurable changes in soil health under varying management practices. The objective of this experiment was to evaluate the effects of long-term (>77 years) manure and inorganic nitrogen (N) fertilizer on soil health and determine the interrelationship among the measured soil bio-physicochemical indicators. The study also aims to understand the sustainability of the monocropping maize production system under long-term manure and inorganic N fertilizer management. The experiment site is the historic Knorr–Holden Plot, established in 1910 and continued till today. Over the years, the treatments were constant, with manure as the main factor and N rates as the sub-plot factor. Aligning with advancements in agronomic management, the rates of fertilizer and manure have been revised from time to time. Analysis of soil health indicators showed a significant effect of manure on different labile C & N fractions, soil enzymes, and soil organic matter (SOM). Manure treatment improved C stabilization and reached a C equilibrium for management. Water holding capacity was significantly improved at the wilting point and field capacity for manure treatment. Nitrogen treatments only affected soil pH, cationic exchange capacity (CEC), and P. SOM was determinative for C & N fractions and CEC. SOC can be used as a proxy for soil total N ( $R^2 = 0.98$ ). Water extractable fractions of C and N were interrelated and can be used as determinative factors for each other. Although a monocropping system can be maintained using long-term manure application, other conservation practices such as crop rotation and minimal tillage would enhance sustainability efforts.

<sup>2</sup> Rothamsted Research - Sustainable Soils and Crops, Harpenden, UNITED KINGDOM

<sup>3</sup> Rothamsted Research - Net Zero and Resilient Farming, North Wyke, UNITED KINGDOM

The Rothamsted Long-Term Experiments (LTEs) in the UK include the 'Classical' experiments established by Lawes and Gilbert at Rothamsted in 1843-1856. They are the oldest continuous agronomic experiments in the world. Originally established to examine the effect of inorganic fertilisers and organic manure on crop yield and nutrient cycling primarily, they have become increasingly important as a platform to conduct research on aspects of the key societal challenges of sustainable agriculture, food security and climate change. The long history of different treatments on the LTEs has resulted in a gradient of measurable soil physical, chemical, and biological properties and functions, on the same soil type and under the same climate, which collectively define 'soil health'. Here we introduce some of the key findings on the relationship between agronomic management and soil health on the Rothamsted LTEs.

Most obviously, long-term application of fertilisers and limes have affected nutrient availability, and organic manure application has increased soil organic carbon (SOC). There are differences in the persistence of SOC fractions with management, affecting long-term sequestration. Long-term management, and especially its effect on soil nutrients and SOC, affects the soil microbiology including the microbiome and the abundance of genes that control soil functions. There is an observed relationship between management, SOC, and soil physical properties on the LTEs, with implications for soil structure and its stability, the ease with which soil may be cultivated, and the ability of soil to support root penetration. Furthermore, SOC, soil structure and soil microbiology combine in distinct associations to control important soil functions such as nutrient delivery to plants, the retention and transmission of water, and the ability of soil to be a sink or source of greenhouse gases.

The Rothamsted LTEs, within the family of global LTEs, continue to yield new insights into the properties and functions of soils and how they may be managed to achieve soil health and sustainability goals in agricultural systems.

<sup>6</sup> ARS, FORT COLLINS, USA

<sup>7</sup> NC STATE UNIVERSITY, RALEIGH, USA

Soil tests and resulting fertilizer recommendations developed over half a century ago were the product of state-level research. Soil-test based recommendations have recently come under scrutiny for various reasons including a lack of current research, inconsistent terminology, and different soil test methods and fertilization philosophies among geographic regions and states within a region. The amount of historical correlation and calibration data to support recommendations and resources to refine recommendations has varied widely among states in the U.S. To bridge differences among states and provide transparency and confidence in soil testing, we have developed the Fertilizer Recommendation Support Tool (FRST) project. Although FRST started by comparing nutrient recommendations for phosphorus (P) and potassium (K) in 14 southern states, the project currently includes researchers from 44 states and one U.S. territory, 3 not-for-profit organizations, and 4 U.S. Department of Agriculture agencies. This collaborative national project involves over 100 soil fertility research and extension personnel. FRST activities include a national soil fertility survey, the development of a minimum dataset for P and K soil fertility trials, a standardized relative yield equation and critical soil test level model for the FRST tool, development of a relational database, and the decision support tool. Activities and accomplishments from FRST will be presented.

### 4. Soil health in achieving the Sustainable Development Goals 4.04 131145 - Dynamics and functions of soil organic matter under new and traditional amendments

#### FROM LTE DATA TO THE SUSTAINABLE CONTROL OF SOIL FERTILITY

##### Authors

T. PUTELAT, A.P. WHITMORE

Rothamsted Research - Net Zero and Resilient Farming, Harpenden, UNITED KINGDOM

Sustainable agriculture requires that soil fertility be optimal to maintain levels of food production whilst also maintaining environmental quality and even improving both together. Like inorganic fertiliser, organic amendments such as manure can increase crop yield and could partly replace artificial nitrogen, but we need a multi-year strategy, because yields may decrease when amendments cease. Other measures to manage arable land such grass and clover leys used in rotation can also enhance crop yield and mitigate soil degradation. Here we propose a way to assess the sustainability of agricultural practices by seeking optimal means for improving the fertility of land that takes account of the dynamics of the yield-enhancing benefits of organic amendments and leys alongside annual applications of artificial fertiliser. Using optimal control theory, we shall present a rational basis for combining applications of inorganic fertiliser and organic matter treatments of arable land to a sequence of crops grown in consecutive seasons that ensures maximum profit from crop production and improves soil fertility. Instead of a complex mechanistic approach, we use the empirical idea of a nutrient response curve, which is extended to include both the effects on yield of the nutrients themselves and also the long-lasting benefits of different types of organic matter management using ad hoc recurrence relations to model the carry-over of soil carbon and nitrogen from one season to the next. We will discuss useful key features of the design of an organic manuring long-term experiment at Rothamsted which allowed for the selection and the parameter identification of a single nutrient response curve valid for different organic treatments. In the context of the field experiment used and the economic conditions assumed, our control theory approach suggests that growing wheat for four years in rotation with one year of a ley can both reduce the use of nitrogen fertilisers and maximise the farmer's annual profit compared to other organic amendments.

<sup>5</sup> Western Sydney University, Sydney, AUSTRALIA

Soils provide 98.7% of the calories consumed by humans, but our near-exclusive focus on using soils to produce food, fibre, and energy (biomass) through agricultural systems is now causing substantial soil degradation. Here, we show that although soil provides numerous functions upon which planetary survivability depends, the accelerating soil degradation caused by focussing largely on a single function (biomass production for food, fibre, and energy) is occurring at the expense of other critical planetary functions – these are 'trade-offs' in soil functionality. In particular, we focus on how land-use change for biomass provision is rapidly decreasing the ability of soils to regulate the carbon pool, with this contributing to climate change, decreasing the ability of soil to cycle the nutrients that sustain plant growth, to protect the 25% of global biodiversity that is found in soil, and to cycle the Earth's freshwater supplies. We demonstrate that soil organic carbon plays a central role in soil multifunctionality and is a master indicator for soil functioning. Given the threats facing humanity and their economies, it is imperative that we recognize that Soil Security is itself an existential challenge and that we need to increase our focus on the multiple functions of soils for long-term human welfare and survivability of the planet.

#### 4. Soil health in achieving the Sustainable Development Goals 4.07 132182 - Soil microbiomes - Importance for climate resilient future, degraded lands restoration and plant health control

##### HOW THE SOIL MICROBIOME COULD BE ENHANCED BY VERICOMPOSTING STRATEGIES: AN EXPERIMENTAL CASE

C. BASSET<sup>1</sup>, Q. LAMBERT<sup>1</sup>

<sup>1</sup> CNAM, Laboratoire Equipe Sécurité Défense, PARIS, FRANCE

<sup>2</sup> Association la Ferme Blue Soil, DIEULEFIT, FRANCE

<sup>3</sup> IRSN, Health & Environment Division, FONTENAY-AUX-ROSES, FRANCE

Food security depends primarily on growers which intrinsically rely on the capacity and condition of soils to deliver functions and services that are mostly provided by healthy soil microbiomes. The need for alternative solutions to fertilizers and pesticides and better sustainable soil management surges into the farming community as production cost and soil depletion increase. Vermicomposting has been accepted as an environmentally beneficial waste stabilization process for transforming organic wastes into high-value organic amendment. In the framework of soil bioremediation and soil food web modeling, vermicomposting is considered as an evolving sustainable technology providing soil microorganisms stored into their gut microbiome. In this study we aim to highlight the key role of earthworms, especially the potential of *Eisenia Fetida*, as significant indigenous microorganisms (IMO) accumulators and an alternative solution in remediating soil microbiome and restoring soil functions. The experimentation takes place into a vineyard in the southeast of France that applies agroecological practices for 5 years and has a non-optimized system (no irrigation, no fertilizers, no pesticide treatments). The vermicompost have been made with the Soil Food Web method of Dr. Elaine Ingham. Vermicomposting was a necessary prior stage for one year to develop the microorganism's diversity and obtain the second and third soil trophic levels. The earthworms were fed with local organic matter in order to inoculate their gut microbiota with IMO. Once mature, the earthworms' substrates were removed in order to extract and breed the IMO produced by the earthworms into a food-enriched oxygenated water, called Vermicompost Oxygenated Tea (VOT). From April to June 2023, the VOT were used as foliar sprays to protect plants from diseases and applied to soil. Preliminary results show that VOT reduced 3 times disease of leaves vines ( $p < 0.001$ ) (Fig 1), reduced water retention time ( $P < 0.001$ ) (Fig 2) and increased soil penetrability ( $P < 0.001$ ) (Fig 3) for the experimental plot compared to agroecological and control plots.

Fig 1. Disease infection (%) in function of soil treatment for year 2023. Significant difference at  $p < 0.001$ .

Fig 2. Soil water retention time (s) in function of soil treatment for year 2023. Significant difference at  $p < 0.001$ .

Over the last century, natural habitats and semi-natural environments have been under increasing environmental pressure, leading to significant changes and a decline in biodiversity. The soil is fundamental to terrestrial ecosystem function and environmental health, contributing significantly to support and regulation services. To address these challenges, a new resilience index named Biodiversity Soil Resilience (BSR) is proposed. This index focuses on the intricate relationship between biodiversity and soil health. It involves a comprehensive analysis of soil biodiversity, with a particular emphasis on entomopathogenic nematodes (EPN), entomopathogenic fungi (EPF), earthworms, and soil microarthropods. Numerous studies support the crucial roles of these components in ecosystem resilience, offering diverse benefits that contribute to environmental stability. For example, entomopathogenic nematodes (EPN) and entomopathogenic fungi (EPF) play a significant role in biological control, the food chain, nutrient cycling, adaptability, and interactions with soil. Earthworms enhance soil aeration, promote the mixing of organic and mineral material, increase microbial biomass, provide biological control against pathogens, and foster beneficial symbioses. These organisms exhibit adaptability to various environmental conditions, contributing to the ecosystems' ability to withstand and recover from environmental stresses. Microarthropods, including mites and collembola, also play a crucial role in the BSR-Index by contributing to soil properties such as decomposition, nutrient cycling, soil structure, biodiversity, adaptability, and resilience. Additionally, they engage in fundamental interactions with vegetation and other microorganisms, further influencing ecosystem health. A key innovation in this research is the development of a dedicated app/software for real-time data collection in the field. This tool streamlines the gathering of information on specific organisms and contributes to a global database of soil biodiversity data. The BSR-Index is envisioned as a monitoring tool for the scientific community and government authorities. The Index, incorporating environmental stresses, soil biodiversity, and soil biological quality (QBS-ar and QBS-e), supported by chemical and physical parameters, aims to enhance our understanding of ecosystem health and promote informed decision-making for a resilient and sustainable future.

### 4. Soil health in achieving the Sustainable Development Goals

#### 4.09 133435 - Optimization of plant-soil-microbe interaction under crop diversification

##### CROPPING SYSTEMS FOR SOIL HEALTH: DOES DIVERSITY MATTER?

T. SIZMUR

University of Reading, Reading, UNITED KINGDOM

In cropping systems there are three primary means to achieving plant diversification: (i) diversifying crop rotations, (ii) intercropping, and (iii) using cover crops. The choice of which cash crops to grow in rotation or to intercrop is highly constrained. However, cover crops grown as part of a crop rotation during periods of the rotation when the soil would otherwise be bare are primarily grown to improve soil health. Unlike rotation diversification and intercropping, cover crops offer a promising means to combine a diverse mixture of plants from a variety of different plant families with contrasting physiology, elemental stoichiometry, or rhizosphere microbial community. In theory, any combination of plants could be grown without fundamentally changing how or when the preceding or proceeding cash crop is managed or harvested. Therefore, cover crops are the most flexible means to increasing plant diversity on farms.

Several experiments have observed greater delivery of functions where more diverse mixtures of plants are grown. However, this observation can often be explained by the 'selection effect'. The 'selection effect' states that functionally efficient species are more likely to be present within a mixture as the number of species increases. This phenomenon can be controlled for statistically by testing all species within a mixture individually and nesting them within a 'single crop' factor. The 'single crop' factor is then compared with the mixture and the difference represents a real interaction between the species in the mixture. This real interaction, caused by a scientifically explainable mechanism, is known as 'complementarity'.

In this talk I will provide examples of where we have observed complementarity and where we have not observed complementarity in experiments undertaken in laboratory and field experiments employing plant mixtures established in crop rotation, intercropping and cover cropping scenarios. I will particularly focus on the possible mechanisms for the synergistic effect observed when returning biochemically contrasting cover crop residues on soil microbial biomass and carbon storage.

#### SOIL AGGREGATE STABILITY ALONG A GRADIENT OF FLOODING INTENSITY IN THE RIPARIAN ZONE: THE ROLE OF ROOT FUNCTIONAL TRAITS

P. HUANG<sup>1</sup>, Y. RAN<sup>1,3</sup>, Y. LIU<sup>1,3</sup>, K. ZHU<sup>1,3</sup>, X. WANG<sup>1,3</sup>, X. YI<sup>1,3</sup>, Y. WANG<sup>1</sup>, M. MA<sup>1</sup>, S. WU<sup>1</sup>, J. ZHANG<sup>2,3</sup>

<sup>2</sup> Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

<sup>3</sup> University of Chinese Academy of Sciences, Beijing, CHINA

Soil aggregates in riparian zones serve as the foundational matrix for critical ecosystem services, yet their stability is intricately linked to the functional traits of plants during rehabilitation. Flooding, a common stressor in these ecosystems, has the potential to alter plant communities and their functional traits, yet the role of these traits in aggregate turnover and stabilization remains poorly understood. To bridge this knowledge gap, we conducted a thorough investigation into the soil aggregate turnover in a typical riparian zone of the Three-Gorges Reservoir. We closely tracked water level fluctuations and their impacts on vegetation, using undisturbed soil sampling and sieving techniques to assess aggregate size distribution dynamics. Additionally, we employed on-site plant quadrat surveys, minirhizotron observations, and lab analysis of above- and below-ground traits to assess the changes and relative contributions of plant functional traits to aggregate stability. Controlled indoor experiments further clarified the mechanisms by which root functional traits influence soil aggregate formation and stability. Our findings revealed that soil aggregate stability decreased significantly with the increasing flooding intensity, but not in a linear fashion. Oxides played a crucial role in aggregate stability under intense flooding, while organic carbon dominated under milder conditions. We observed significant variations in above- and below-ground biomass with flooding intensity, and species diversity had contrasting effects on small macro-aggregate formation. Perennial herbs with fibrous root systems were essential for soil aggregate stability under intense flooding, while plant diversity was critical under milder conditions. Root volume density mediated the effects of plant diversity on riparian soil aggregate stability. This study highlights the complex interactions between flooding, plant functional traits, and soil aggregate stability in riparian zones. Understanding these dynamics is crucial for effective management and restoration of these vulnerable ecosystems.

### 4. Soil health in achieving the Sustainable Development Goals 4.17 133569 - Revitalization of mining residue deposits

#### DEVELOPING A REVEGETATION TOOLBOX FOR MINE RESIDUE DEPOSITS IN THE SOUTHERN AFRICAN REGION.

S. NORRA

Potsdam University, Potsdam, GERMANY

#### **Body**

In southern African countries, such as South Africa or Namibia, numerous mine residue deposits of various commodities such as Gold, Coal, Copper, Lead, Zinc or Uranium are potential threats to the environment. Water resources can be contaminated or dust from these deposits can be resuspended and pollutes the atmosphere. A vegetation cover would improve the situation but often the climate and the soil properties are limiting the spontaneous growth of plants. To identify and implement sustainable solutions the Mine Water Management Network was established in 2021 to develop adapted solutions solving the specific challenges at the specific deposits. Since in these environments, water is often a scarce resource it is one aim to use mine waste water for irrigation of revegetation measures. Since at some sites, the mine water has high salt or heavy metal contents, adapted solutions have to be developed to at least semi-purify the mine waste water before use. This must not be always a high end reverse osmosis system; local materials form concrete works or water treatment facilities also potentially can be used. Furthermore, it has to be decided which plants can be grown on the deposits, able to cope with specific site conditions. In case of the absence of potential contaminations crops can be planted. If the contamination of the food chain is too serious, plants for biomass and energy production can be chosen. Under very dry climates, at least contributions to support biodiversity can be undertaken. In all of these cases a sound analyses of the soil physics and the continuous spatial monitoring of soil water content is important to optimize the irrigation modes.

Thus, many aspects have to be considered to successfully revegetate MRD under dry conditions. Here, the project WaMiSAR (Sustainable and climate adapted water management in mining of the Southern African Region) aims to develop and compile a revegetation toolbox that contains all necessary tasks for revegetation in this region.

### 4. Soil health in achieving the Sustainable Development Goals 4.18 133571 - Contaminants of Emerging Concerns in Soil: Occurrence, Fate and Transport, Toxicity and Remediation

#### EMERGING CONTAMINANTS IN THE WASTEWATER-SOIL-PLANT CONTINUUM

JAY GAN, QINGYANG SHI, RACHEL FU, SHERRY WU, STACIA DUDLEY, JANE XIONG, LAUREL DODGEN

Department of Environmental Science, University of California Riverside, CA 92521, U.S.A.

Municipal treated wastewater and biosolids are historically under-utilized resources but are finding increasing uses in agriculture. Due to urbanization and climate-change induced water scarcity, treated wastewater is viewed as a valuable water source for agricultural irrigation, especially in arid and semi-arid regions. Biosolids, the primary by-product of wastewater treatment, are widely used as soil amendments for their nutrient value. Irrigation with treated wastewater and application of biosolids or animal waste introduce numerous contaminants of emerging concern (CECs) into our food crop production systems. Transfer of CECs in these “waste” sources from soil to our food produce constitutes a potential food safety and human health risk. We have carried out systematic research to evaluate uptake of common CECs into vegetables and to mechanistically understand their plant metabolism pathways. A comprehensive risk assessment and management of CECs in agroecosystems is constrained by multiple factors, the utmost of which is the enormous number and diverse characteristics of CECs. Here we provide an overview of current knowledge, and then outline a bottom-up tiered approach as the path forward to identify priority CECs to better address this concern. We further propose several strategies to minimize the potential risk of CECs during the beneficial reuse of treated wastewater and biosolids. This research contributes to environmental sustainability while ensuring safety in beneficial reuse of these valuable resources.

### 4. Soil health in achieving the Sustainable Development Goals 4.19 133576 - Soil N<sub>2</sub>O emissions: understanding the underlying mechanisms and assessing the impact of soil management strategies

**NITROUS OXIDE DRIVERS IN NATURAL AND MANAGED MEDITERRANEAN ECOSYSTEMS, ARE WE OVERESTIMATING EMISSIONS?**

S CASTALDI, E GRILLI, H K ISHAQ

DISTABIF, University of Campania Luigi Vanvitelli, Caserta, ITALY

Nitrous oxide (N<sub>2</sub>O) is a microbial by-product and/or intermediate of reaction, and terrestrial ecosystems, where the flow of N is accelerated by anthropogenic causes, are considered its main global source. Different co-factors contribute to switch and magnify N<sub>2</sub>O fluxes in soils, such as pore water saturation and high respiration rates in soil hotspots. Finer drivers might be represented by the quality vs quantity of available substrates, natural and artificial inhibitors of microbial processes, competition for substrates. Contrarily to the prediction of high N<sub>2</sub>O fluxes from macro drivers, such as fertilization or tillage of organic soils, the causal relationship between N<sub>2</sub>O emissions and N and C cycle dynamics and ecosystem characteristics is less clear where fluxes are lower. This is often the case of Mediterranean ecosystems, in particular in southern areas where drier climate and specific conditions might result in even lower fluxes than expected, leading to overestimating their global contribution. We present some examples including drivers of N<sub>2</sub>O fluxes in Mediterranean southern areas of Europe, in monospecific coppices, in leguminous fields, in pastures under conventional and adaptive management, in agricultural sites. Indications might be relevant for adaptation strategies and C farming and mitigation policies.

### 4. Soil health in achieving the Sustainable Development Goals 4.20 133577 - Sustainable soil management and agronomic practices for carbon farming: challenges and opportunities

INCREASING SOIL CARBON AND SOIL HEALTH IN PRODUCTIVE SYSTEMS IN COSTA RICA, MEXICO, AND TOGO THROUGH THE FAO'S RECARBONIZATION OF AGRICULTURAL SOILS (RECSOIL) INITIATIVE

S USTINOV, M BROWN, G PERALTA, V SAYNES SANTILLAN, N RODRIGUEZ EUGENIO, C OLIVERA

FOOD AND AGRICULTURE ORGANIZATION OF THE UNITED NATIONS, ROME, ITALY

The Food and Agriculture Organization of the United Nations (FAO) has launched the Recarbonization of Agricultural Soils (RECSOIL) initiative, being implemented through its Global Soil Partnership. RECSOIL focuses on increasing or maintaining soil organic carbon (SOC) stocks and improving soil health in agricultural and degraded lands through the adoption of sustainable soil management (SSM). This study observes the impact of RECSOIL in pilot implementation sites in Mexico, Costa Rica, and Togo.

RECSOIL identified implementation sites using the Global Soil Organic Carbon Sequestration Potential (GSOCseq) map and atlas of Global Change Issues, selecting sites with high SOC sequestration potential and convergence of global issues. Site-specific SSM practices were selected with producers, technicians, and scientists. The "Protocol for the assessment of Sustainable Soil Management" and "A protocol for measurement, monitoring, reporting and verification of soil organic carbon in agricultural landscapes" (GSOC-MRV Protocol) were followed to establish a baseline of SOC stocks and soil health status. The FAO's EX-Ante carbon Balance Tool (EX-ACT) is used to monitor greenhouse gas (GHG) emissions.

Agave farmers in Mexico identified erosion and soil moisture retention as concerns while corn farmers identified biodiversity loss and pests as major soil threats. SSM efforts would mitigate up to 59 tons CO<sub>2</sub>eq annually across 140 hectares through cover cropping in agave crops and through intercropping in corn crops, while addressing other soil threats identified.

In Costa Rica, approximately 45 dairy and coffee farmers would reduce GHG emissions up to 872 tons of CO<sub>2</sub>eq annually across 500 hectares through grazing management, erosion control, and enhanced residue cover.

In Togo, the degradation of native ecosystems necessitates a shift in management. Recommended practices included raising small livestock and facilitating agroforestry to promote soil restoration. New management practices would reduce GHG emissions by approximately 146 tons CO<sub>2</sub>eq annually across 250 hectares.

SSM practice implementation through RECSOIL is demonstrating to be a powerful tool for improving soil health and increasing resilience.

<sup>7</sup> iDiv/University of Leipzig, Leipzig, GERMANY

Soil animals represent up to 27% of all known species worldwide, and many taxa are frequently used as bioindicators of disturbance, land use management and soil health. This is because they contribute to the provision of important ecosystem services to human beings, in all categories: cultural, provisioning, supporting and regulating. Services provided include soil formation, habitat for organisms, decomposition and nutrient cycling, climate regulation, pollination, seed dispersal, biological control of pests and pathogens, preservation of cultural heritage, recreation, food, fiber and fuel production, source of pharmaceuticals and genetic resources, water availability and quality, and erosion control. In this way they also help achieve the United Nations Sustainable Development Goals (SDGs). However up to now, few attempts have been made to assess and value their multiple services provided in different land uses worldwide.

Both the FaunaServices and the sOilFauna projects, involving a large number of collaborators worldwide aim to assess various services provided by the soil macrofauna communities sampled using standard methods (handsorting following TSBF/ISO) in both natural and anthropogenic ecosystems. This is being achieved by using data on the abundance (density and biomass) of up to 12 main taxa of soil macrofauna, among a wider list of almost 45 taxa collected in over 8500 sites worldwide (sOilFauna) and 1500+ sites in the Amazon and Atlantic Forest biomes (FaunaServices). Foodweb models and knowledge on biological and stoichiometric relationships of the taxa are being used to assess C, N and P cycling, pest control, decomposition, and bioturbation rates. By calculating these functions and using current market values, avoided and replacement costs, the value of a range of services will be estimated in contrasting land uses to assess opportunity costs and benefits associated with management and conservation of soil fauna communities. These actions intend to support policy development, awareness raising, and the achievement of goals associated with the CBD's International Initiative for the Conservation and Sustainable Use of Soil Biodiversity.

### 4. Soil health in achieving the Sustainable Development Goals 4.25 133607 - Black Soils: their importance for Food Security and Carbon Neutrality

#### "LISHU MODEL"- AN INTENSIVE YET SUSTAINABLE SYSTEM FOR THE BLACK SOILS OF NORTHEAST

B. LI<sup>1</sup>, T. REN<sup>1</sup>, G. WANG<sup>2</sup>, H. ZHOU<sup>1</sup>

<sup>1</sup> College of Land Science and Technology, China Agricultural University, BEIJING, CHINA

<sup>2</sup> Lishu Experimental Station, China Agricultural University, Lishu, CHINA

The black soils of Northeast China contribute to about 25% of national grain production. The traditional intensive farming system, however, has led to severe soil degradation (e.g., erosion, compaction, and losses of organic carbon and biodiversity), which threatens grain security in China. To overcome these problems, we introduced the technology of conservation farming that consists of crop rotation, minimum or no tillage, and maintaining permanent crop residue on soil surface in maize production. We also developed a promotion system, to publicize and transfer the concept and technologies of conservation farming to local farmers with collective efforts from scientists, government agencies, industries, and local farmers. The conservation farming practices, along with the extension system, is named the "Lishu Model" in China. With continuous efforts for more than 10 years, we have established more than 100 "Lishu Model" research and development bases in the four provinces of Northeast China, and the new farming system is being practiced in an area over 3.3 million ha. The major advantages of the "Lishu Model" are: (1) improved soil water retention and supply capacity; (2) buildup of soil organic matter (SOM concentration was increased by more than 10%) and a reduction of chemical fertilizer application (by about 20%); (3) reduction of runoff (by 60%) and soil loss (by about 80%); (4) greater crop yield (5%~10% increase over the conventional system); (5) greater soil biodiversity (e.g., 6 times more earthworms than that of the conventional system) and improved soil biological properties; (6) improved farming profits (by saving costs as much as 1000 - 1400 yuan/ha) and lower carbon emission (by reducing 25 - 30% fuel consumption); and (7) improved corn grain quality. We conclude that the Lishu Model achieves the synergies between soil health, food security, and climate change mitigation, and will become the mainstream farming technology in Northeast China, which will significantly contribute to soil quality improvement and expansion of agricultural production capacity.

#### CARBON STORAGE IN CROPLAND SOILS: INSIGHTS FROM IOWA, UNITED STATES

J. JORDAHL <sup>1</sup>, M. MCDANIEL <sup>2</sup>, B. MILLER <sup>2</sup>, M. THOMPSON <sup>2</sup>, S. VILLARINO <sup>2</sup>, L. SCHULTE <sup>3</sup>

<sup>1</sup> Iowa State University, Bioeconomy Institute, Ames, USA

<sup>2</sup> Iowa State University, Agronomy Department, Ames, USA

<sup>3</sup> Iowa State University, Department of Natural Resource Ecology and Management, Ames, USA

Restoration of soil organic carbon in agricultural soils is imperative to sustaining crop production and restoring other ecosystem services. We compiled long-term studies on the effect of management practices on SOC from black soils in Iowa, USA, to highlight constraints on detecting changes in SOC and to inform research needed to improve SOC measurement and management. We found that strip-tillage and no-tillage increased SOC by 0.28-0.33 Mg C ha<sup>-1</sup> yr<sup>-1</sup> compared to conventional tillage. However, diversifying crop rotations with extended rotations, and supplementing synthetic fertilizer with animal manure, had highly variable and inconsistent effects on SOC. Conversion of cropland to perennial grassland increased SOC by 0.21-0.74 Mg C ha<sup>-1</sup> yr<sup>-1</sup>. Improved predictions of changes in SOC require experiments and observations that can identify and disentangle multiple sources of variability; whole-profile SOC monitoring; monitoring the effect on SOC in long-term studies of multiple conservation practices used in combination; and effective collaboration between field soil scientists and modelers.

**Keywords:** Black soils, Mollisols, soil variability, detection of change, whole-profile SOC

#### ONSET TIME AND ACCRETIONARY FORMATION OF MOLLISOLS IN NORTHEAST CHINA

Z GANLIN <sup>1</sup>, H LONG <sup>2</sup>, F YANG <sup>3</sup>

<sup>1</sup> Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

<sup>2</sup> Nanjing Institute of Geography & Limnology, Chinese Academy of Sciences, Nanjing, CHINA

<sup>3</sup> Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

Mollisols are one of the most fertile soils in the world thanks to the thick organic-rich mollic layer. It remains unanswered questions when Mollisols started to form and how thick mollic layer formed, due to the complex nature of soils and the limitations of soil dating techniques. In this study, by dating diverse materials including charcoal, buried mollic layer and naturally developed mollic layer, with both <sup>14</sup>C and OSL dating techniques, we determined that prevalent formation of Mollisols in northeast China commenced during the Bølling-Allerød interstadial period. This is much earlier than previously reported age data by using <sup>14</sup>C dating which dominantly showed that Mollisols started to form during the Holocene in northeast China and other parts of the world. By comparing the OSL age and <sup>14</sup>C age we further proposed that formation of Mollisols followed an accretionary pedogenic model, which provided a new perspective to understand the forming mechanisms for such thick mollic layer in northeast China. By this model, thick mollic layer formed as a result of simultaneous accumulation of soil organic matter and continuously deposited dust (loess). According to age data we estimated that on geomorphically stable land surface, Mollisols formed at a rate of ~6 cm ka<sup>-1</sup>. Beside, this model well explains the generally underestimated onset time of Mollisols by <sup>14</sup>C dating of bulk soils or soil organic fractions.

**Keywords:** Mollisols, Black soils, soil age, soil dating, OSL

<sup>5</sup> Food and Agriculture Organization of the United Nations, Rome, ITALY

<sup>6</sup> Food and Agriculture Organization of the United Nations, Rome, ITALY

Black soils, characterized by their thick, dark horizons enriched with organic matter, epitomize highly fertile soils. However, their fertility decreases rapidly with intense and non-sustainable land utilization, leading to degradation processes such as soil erosion, nutrient depletion, pollution, compaction, salinization, and acidification. Notably, these soils may become significant contributors to global greenhouse gas emissions, primarily due to substantial losses in soil organic carbon (SOC), when production practices detrimental to the soil are used for crop and livestock production. Despite these challenges, black soils play a pivotal role in global food production. This work delineates the progress of the FAO's International Network of Black Soils (INBS). Since the establishment of the INBS, experts in the network have developed a general definition of black soils, published a Global Status of Black Soils report, and launched a Global Black Soil Distribution Map. The key publications highlighted that black soils cover an approximate area of 725 million hectares, with the Russian Federation, Kazakhstan, and China collectively harboring over half of this expanse, and extensive areas also in Argentina, Mongolia, Ukraine, United States of America, Colombia, Canada and Mexico. Agriculturally, these soils underpin significant proportions of global crop yields, contributing with 66% of sunflower seeds, 30% of wheat, and 26% of potato outputs. The SOC content in the upper 30 cm of these soils is estimated at 56 Petagram. Sustainable management of black soils is imperative for ensuring world food security and addressing climate change on a global scale.

**Keywords:** Black soils, INBS, Soil organic carbon, Food security

#### THE CHALLENGE OF PREDICTING SOIL ORGANIC CARBON VARIABILITY IN TEMPERATE AGRICULTURAL LANDS USING OPEN PREDICTORS: INSIGHTS FROM REMOTE SENSING

C SEGURA QUIRANTE<sup>1</sup>, A L NEAL<sup>1</sup>, L CASTRO-SARDINA<sup>2</sup>, P HARRIS<sup>1</sup>, M J RIVERO<sup>1</sup>, L CARDENAS<sup>1</sup>, G IRISARRI<sup>1</sup>

<sup>1</sup> Rothamsted Research North Wyke, Okehampton, UNITED KINGDOM

<sup>2</sup> IFEVA, Universidad de Buenos Aires, CONICET, Facultad de Agronomía, Buenos Aires, ARGENTINA

This study addresses the need for effective monitoring of soil organic carbon (SOC) in agricultural management, particularly caused by land-use change. Conventional methods for SOC measurement are often challenging, time-consuming, and expensive. Focusing on temperate farmland, and using a ten-year dataset generated on mixed temperate farmland of the North Wyke Farm Platform long-term experiment (LTE) in southwest England, the study employs field-based statistical models, and compares linear, additive, and mixed regression models to predict soil organic carbon (SOC) based on environmental variables. We distinguished between freely accessible measures including remote sensing (RS) techniques (open) and those requiring direct measurement or farmer questionnaires (closed), evaluating their relative utility in providing a cost-effective approach to assess soil organic carbon stocks. Generalized Additive Models (GAMs) proved most effective in predicting space-time SOC variability. Total nitrogen (TN) was as the strongest predictor when combining open and closed factors. Excluding TN, ploughing management, soil units, aspect, and temperature were identified as significant predictors. The best-fitting open data GAM—incorporating a RS-derived Ecosystem Services Provision Index (ESPI), aspect, and slope—provided acceptably accurate SOC predictions which were practical and cost-effective to generate at landscape scales. This model offers a valuable tool for understanding SOC variations in temperate farmland, providing insights into the impact of different environmental and management factors. The combination of LTE and RS datasets offers a promising avenue for accurate and efficient monitoring of SOC changes, contributing to the development of sustainable and resilient agricultural policies. This model can serve as a decision-support tool for understanding temporal and spatial variations in SOC under different land-uses and management practices.

### 4. Soil health in achieving the Sustainable Development Goals 4.28 133610 - Characterizing and selecting soil health indicators at various scales

#### SMAF SOIL QUALITY INDICES IN TEMPERATE AND TROPICAL AGROECOSYSTEMS

H. AMORIM <sup>1</sup>, A. ASHWORTH <sup>2</sup>, M. NUNES <sup>3</sup>

<sup>1</sup> University of Arkansas, Department of Crop, Soil, and Environmental Sciences, Fayetteville, USA

<sup>2</sup> USDA ARS Poultry Production and Product Safety Research Unit, Fayetteville, USA

<sup>3</sup> University of Florida, Department of Soil, Water, and Ecosystem Sciences, Gainesville, USA

Initially developed for US agroecosystems, the Soil Management Assessment Framework (SMAF) can assess soil health as affected by management practices and land use changes. Recently, SMAF has been applied as a soil health assessment tool in Brazil, but the sensitivity of SMAF scoring functions and their relationship with ecosystem services are not yet proven for tropical, highly weathered soils. This study aimed to assess SMAF soil quality indices (SQI) in agroecosystems in the US Mid-South and Brazil, and investigate the ability of SMAF to differentiate management practices and the relationship of SMAF with ecosystem services. For this, we compiled 12 SMAF studies published in Brazil ( $n = 206$ ) and 61 studies published for the Mid-South US ( $n = 553$ ). Management practices were defined based on levels of soil disturbance. Analysis of variance was used to compare soil indicators [pH, P, K, bulk density (BD), aggregate stability (AGS), soil organic C (SOC), and microbial biomass C (MBC)] and SMAF soil quality indices between conservation and conventional agricultural practices. Linear regressions assessed the relationship between SMAF SQI and SOC stocks. Reducing soil disturbance through conservation management increased SOC, MBC, and AGS, and reduced BD in both regions. In the US Mid-South, perennial systems had the highest SQI ( $p < 0.05$ ; 0.81), followed by no-till (0.75), and reduced (0.73) and conventional tillage (0.69). In Brazil, SQI in perennial systems (0.74) was higher than no-till ( $p < 0.05$ ; 0.64), which did not differ from reduced (0.63) and conventional tillage (0.62). SMAF scoring functions need to be revised to better capture the impacts of conservation agricultural practices on soil health in tropical regions. The positive relationship between SMAF SQI and SOC stocks ( $R^2 = 0.33-0.66$ ) indicates that SMAF relates to the ability of agroecosystems to provide regulating ecosystem services. After revision and calibration, SMAF can be a valuable tool to demonstrate the benefits of conservation practices on soil health in tropical regions.

##### CHARACTERIZING SOIL CLAY MINERALS USING MID-INFRARED SPECTROSCOPY

Y HUANG, W NG, B MINASNY, A B MCBRATNEY

School of Life and Environmental Sciences & Sydney Institute of Agriculture, The University of Sydney, Sydney, AUSTRALIA

Clay minerals determine the physio-chemical properties of soils, and properties such as cation exchange capacities and swell-shrinkage behaviour are particularly affected by clay types. The composition of clay minerals is usually determined by X-ray diffraction (XRD) analysis. However, separation of clay fraction through particle-size analysis is time-consuming, and identification of clay minerals requires multiple treatments of oriented slide samples. Fundamental vibrations of minerals fall within the mid-infrared (MIR) region (2500–25,000 nm), and various soil properties have been successfully predicted by MIR spectroscopy. Hence, MIR spectroscopy serves as a promising tool for clay mineral determination due to its low cost and high throughput. This study aims to use MIR spectroscopy to predict the abundance of clay minerals in soils and identify the dominant clay mineral type. Eight mineral types were chosen as targets: calcite, chlorite, gibbsite, kaolinite, mica, montmorillonite, quartz, and vermiculite. A total of 7193 soil samples were obtained from the national database of the Kellogg Soil Survey Laboratory (KSSL) in Lincoln, Nebraska, USA. Their dominant clay mineral types were assessed by XRD analysis, and the amount of each mineral was quantified into five grades based on their peak heights. MIR spectra were trimmed to 4000–600 cm<sup>-1</sup> and pre-processed by Savitzky-Golay (SG) smoothing, followed by Standard Normal Variate (SNV) transformation. Partial least squares regression (PLSR) models were built for each of the mineral types, and dominant mineral types were predicted by direct comparison of PLSR results. Over 65% of the dominant mineral types in the testing samples were correctly predicted by PLSR models, and the kappa coefficient was 0.57, indicating a moderate agreement between XRD and MIR results. Furthermore, in 89% of the testing samples, the predicted dominant mineral type ranked within the top three abundant minerals by XRD measurements, implying that PLSR models successfully identified the major clay mineral types. These results provide preliminary outcomes for MIR to differentiate major clay types in soils.

##### ENHANCING A DYNAMIC SOIL ORGANIC CARBON TURNOVER MODEL USING EARTH OBSERVATION DATA

C HENDRIKS<sup>1</sup>, J P LESSCHEN<sup>1</sup>, W MEIJNINGER<sup>1</sup>, A DE WIT<sup>1</sup>, G ROERINK<sup>1</sup>

Wageningen University & Research, Wageningen, THE NETHERLANDS

Soil organic carbon (SOC) is an important soil quality indicator. While in large parts of the world SOC content in agricultural soil is decreasing, awareness on restoring or improving the SOC content is growing. Measures like sowing green manure after harvest or adding compost to the soil, can help increasing the SOC content. Increasing SOC content can make a soil more resilient and increase the overall soil fertility, but it also helps combatting climate change by sequestering CO<sub>2</sub> from the atmosphere. A clear Monitoring, Reporting and Verification (MRV) system is required for the assessment of SOC stock changes and potential SOC stocks. However, because the existing SOC stock is large, the increase is relatively small which makes it difficult to measure on the short term. Dynamic soil organic carbon turnover models can solve this problem by assessing SOC stock changes over longer time periods. The RothC model is a scientific, widely adopted SOC turnover model that requires simple input data that is often available at field level. Assumptions in the input data were made running the model at national level in the Netherlands, but these assumptions seem to be quite rough when running the model at field level. Making use of Earth Observation (EO) data, which can provide additional information on vegetation cover, the growth period of cover crops, grassland renewal, and (cover) crop production, can help improving the model input data. This study shows the effect of replacing some input data of the RothC model by EO data. The model will simulate soil carbon stock changes for time period 2018-2023 (i.e. 6 years) for the whole of the Netherlands with varying spatial resolution (i.e. at postal code level for ~3400 units and parcel level for ~500.000 parcels). In a later stage, the RothC simulations will be validated against soil C-measurements taken in approximately 400 fields as part of the national soil sampling campaign of 2018 and 2024.

<sup>4</sup> University of Santa Maria, Santa Maria, BRAZIL

Current anthropogenic pressures on land, soil, and water resources are unsustainable. Humans are using these resources as if they inhabited 1.75 Earths. Multiple lines of evidence suggest that this overuse of land and water resources is likely to continue into the future. One direct consequence of these changes is the acceleration of land degradation by soil erosion, depleting the soil resources, dispersing sediment and potential sediment-bound pollutants in the environment. To promote more resilient landscape management, it is therefore necessary to develop soil erosion models that can target the most vulnerable zones and guide the implementation of the most appropriate soil conservation strategies.

However, soil erosion processes exhibit significant variability both in space, depending on the soil and landscape characteristics, and in time, ranging from the effects of the temporal dynamics of successive rainfall events to seasonal variations influenced by climate or by anthropogenic land use changes. These spatial and temporal variations interact nonlinearly and are subject to thresholds, highlighting the complexity of erosion processes. It is very complex to integrate all these processes in soil erosion models, which thus need to be based on strong hypothesis limiting their validity to specific applications.

Therefore, a range of different concepts and approaches has been developed, depending on the modeller's objectives, from non-dynamic, lumped empirical models for generic landscape management to "physically-based" high spatial and temporal dynamic models that can help test research hypotheses. In this study, we will review the application of different soil erosion modelling approaches in contrasting environments to illustrate the capabilities and limitations of the different approaches. We will then attempt to identify the main challenges and recommendations that can be drawn from this exercise.

#### INTEGRATED SOIL EROSION ASSESSMENT: CONCEPTS, APPLICATIONS AND PERSPECTIVES

M. MAERKER

Department of Earth and Environmental Sciences, Pavia, ITALY  
Center for Agricultural Landscape Research, Müncheberg, GERMANY

Soil Erosion processes are threatening global soil resources in terms of loss of fertile topsoil, reduction of soil water storage capacity as well as loss of biodiversity and soil organic matter releasing CO<sub>2</sub> to the atmosphere. Moreover, soil erosion leads also to off-site damages due to the sediments produced that fill up reservoirs or reduce water quality. Especially semiarid areas already suffer in terms of a sustainable agricultural production as well as of providing ecosystem services and functions. The challenges coming along with soil erosion processes are manifold. Thus, a proper assessment of these processes under changing future conditions such as climate and landuse/landcover changes is a prerequisite to allow for a suitable land management. Therefore, the quantification of different soil erosion processes and the prediction of these processes in space and time is needed. In this talk concepts and methods to numerically assess different soil erosion processes are reflected, some case studies presented and future challenges and perspectives of an integrated soil erosion modelling are discussed.

Being a fundamental indicator of soil health and quality, soil bulk density (BD) plays an important role in plant growth, nutrient availability, and water retention. Due to its limited availability of BD in databases, pedotransfer functions (PTFs) has been widely used in predicting BD, while the impact of PTFs' accuracy on soil organic carbon (SOC) stock calculation has not been explored. Herein, we proposed a local modeling approach for predicting BD across EU and UK using LUCAS Soil 2018. Our approach involved a combination of neighbor sample search, Forward Recursive Feature Selection (FRFS) and Random Forest (RF) model (local-RFFRFS). The results showed that local-RFFRFS had a good performance in predicting BD ( $R^2$  of 0.58, RMSE of 0.19 g/cm<sup>3</sup>), surpassing the traditional PTFs ( $R^2$  of 0.40-0.45, RMSE of 0.22 g/cm<sup>3</sup>) and global PTFs using RF with and without FRFS ( $R^2$  of 0.56-0.57, RMSE of 0.19 g/cm<sup>3</sup>). Interestingly, we found the best traditional PTF ( $R^2=0.84$ , RMSE=1.39 kg/m<sup>2</sup>) performed close to the local-RFFRFS ( $R^2=0.85$ , RMSE=1.32 kg/m<sup>2</sup>) in SOC stock calculation using BD predictions. However, the local-RFFRFS still performed better ( $\delta R^2>0.2$  and  $\delta RMSE>0.1$  g/cm<sup>3</sup>) for soil samples with low SOC stock (<3 kg/m<sup>2</sup>). Therefore, we suggest that the local-RFFRFS is a promising method for BD prediction while traditional PTFs would be more efficient when BD is subsequently utilized for calculating SOC stock.

**SOIL NITRIFICATION MICROORGANISMS AND NITROGEN MANAGEMENT IN AGRICULTURAL ECOSYSTEMS**

J. HE

School of Agriculture, Food and Ecosystem Sciences, The University of Melbourne, Melbourne, AUSTRALIA

Nitrification, as a critical component of the nitrogen (N) cycle, is a microbially-mediated oxidizing process from ammonia to nitrate, contributing to enormous N losses of fertilizers through atmospheric emissions of greenhouse gas N<sub>2</sub>O and nitrate leaching to groundwater. The process of nitrification is mainly driven by nitrifying microorganisms, including ammonia-oxidizing bacteria (AOB) which were discovered over 130 years ago in 1890, ammonia-oxidizing archaea (AOA) which were discovered in 2005, and complete ammonia oxidation (termed as comammox) bacteria which were discovered in 2015. This paper will introduce our research on the niche differentiations of these ammonia-oxidizing microorganisms. Our research findings contribute to biological manipulation and N fertilizer management for improved N using efficiency and mitigated N losses in agricultural ecosystems.

**THE 4TH EDITION OF THE WRB HAS A NEW FIELD GUIDE AND NEW HORIZON DESIGNATIONS REPLACING THE FAO GUIDELINES FOR SOIL DESCRIPTION**

P. SCHAD

Technical University of Munich, Chair of Soil Science, Freising, GERMANY

At the 22nd World Congress of Soil Science in 2022 in Glasgow, the 4th edition of the international soil classification system World Reference Base for Soil Resources (WRB) was published. The 32 Reference Soil Groups (first level) of the 3rd edition were maintained but changes were made to the qualifiers (second level) and to the diagnostics in order to sharpen many definitions.

For the first time, WRB received its own Field Guide and its own Horizon and Layer Designations, added as Annexes. Until 2022, the FAO Guidelines for Soil Description were used. This caused many problems:

- The FAO Guidelines were not sufficiently precise.
- In many cases, the FAO Guidelines and the WRB applied different limit values.
- Some characteristics required by the WRB were completely missing.
- And the biggest problem: The FAO classification (1974, 1988) and the WRB (1998, 2006, 2015) adopted many definitions from the US Soil Taxonomy, which descend from earlier issues of the US Soil Survey Manual (example: 'weakly cemented to indurated') and were neither defined in the WRB nor in the FAO Guidelines.

The new WRB Field Guide provides the following:

- Precise definitions of field characteristics.
- Didactical explanations of the characteristics to be surveyed.
- A code system for field characteristics.
- A Soil Description Sheet.

Providing precise definitions for field characteristics is the most important progress of the new WRB edition. Many of them are close to the definitions in current US Soil Taxonomy field documents, which brings WRB and Soil Taxonomy closer together. Among the characteristics described are soil-forming factors (e.g., climate, topography), surface characteristics (e.g., rock outcrops, surface sealings), and all common horizon and layer characteristics (e.g., texture, structure, redoximorphic features). For hand texturing, a simple and precise flowchart was developed.

The Horizon Designations use the well-known master symbols and suffixes of the FAO Guidelines, but more precise definitions are given and some additional symbols introduced.

**Keywords:** WRB, Soil Survey, Field Characteristics, Horizon Designations

<sup>3</sup> Institute of Geology and Mineralogy, University of Cologne, Cologne, GERMANY

<sup>4</sup> 5Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Amsterdam, THE NETHERLANDS

<sup>5</sup> 6State Authority for Mining, Energy and Geology, Hannover, GERMANY

The investigations into carbon sequestration in Plaggic Anthrosols are often based on bulk soil carbon inventories, neglecting considerations of carbon form (particulate or mineral-associated), storage capacity, and chemical composition. Our focus is on the unusually high organic carbon (OC) accumulation in sandy Plaggic Anthrosols and their adjacent reference soils under agricultural use. Despite the commonly assumed significance of fine-sized particles (fraction smaller than 20  $\mu\text{m}$ ) in OC stabilization, their mass proportion is very low in these soils. Soil organic matter (SOM) physical fractionation was performed to assess OC quantity and quality in topsoils (Ap horizon). For the resulting fine fraction smaller than 20  $\mu\text{m}$ , we measured OC concentration, radiocarbon concentration, calculated OC storage capacity and contribution, and analyzed carbon unit chemical composition using solid-state  $^{13}\text{C}$  NMR spectroscopy. These highly sandy soils (80–90%) exhibited OC accumulation surpassing conventionally calculated saturation levels controlled by the proportion of fine fraction. Surprisingly, no correlation was found between topsoil OC concentration in the medium, fine silt and clay sized fraction and the mass percentage of particles smaller than 20  $\mu\text{m}$ . Plaggic Anthrosols and reference soils were comparable in fractional concentration of OC, radiocarbon age, and OM composition. The fine fraction's SOM composition was notably rich in alkyl C, with a minor proportion of O-alkyl C and low percentages of aryl C.

Radiocarbon concentration and conventional radiocarbon age suggested that fine fraction OM in topsoils accumulated low OC inputs from recent photosynthesis and is stored for long periods with high mean radiocarbon ages, not only for Plaggic Anthrosols (F14C:  $0.92 \pm 0.04$ ; 14C: 639 yBP) but also for reference soils (F14C:  $0.93 \pm 0.04$ ; 14C: 575 yBP). It remains unclear if the inherited OM is stable under present-day soil and management conditions. Our data imply specific mechanisms at play in sandy OM-rich agricultural soils for storing substantial amounts of OM beyond a mechanistic explanation based solely on OM association with fine mineral surfaces.

<sup>3</sup> Sorbonne Université, Paris, FRANCE

<sup>4</sup> IRD, Montpellier, FRANCE

<sup>5</sup> CNRS, Paris, FRANCE

A diversity of agricultural practices and systems enable the accrual of soil organic C (SOC) stocks, with variable efficiencies. These C-storing practices increase SOC stocks, either by increasing the inputs of plant biomass or exogenous organic matter, or by decreasing the outputs of SOC reducing SOC mineralisation rates, or both. In the perspective of contributing to climate change mitigation, the temporal stability of the additional SOC stored is critical.

Different approaches can be used to assess the stability of soil organic matter, such as physical fractionation of soil organic matter, chemical extractions, long term incubations and analysis of the thermal behaviour of the organic matter using Rock-Eval© analysis. These address contrasting residence times, such as of months to years (long term incubations), to several decades and centuries (particle size fractionation, Rock-Eval© analysis coupled with PARTYSOC model)

We used the literature and long-term agricultural experiments in which management options (application of exogenous organic matter, conservation agriculture, organic agriculture, agroforestry) result in increased SOC stocks. We investigated the stability of the additional SOC stored, compared to the reference management option.

Methods currently used in the literature to assess the temporal stability of soil organic matter do not address the same SOC kinetic pools. Care must be taken to specify which range of residence times is considered when using any method intending to evaluate the biogeochemical stability of soil organic matter, as well as when using the terms stable or labile.

Management options result in slightly contrasted stability of the additional organic carbon, the application of exogenous organic matter resulting in the most stable additional carbon, compared to management options that increase belowground plant biomass inputs to soil. Carbon storing agricultural management options mobilize different stabilization processes of soil organic matter: chemical recalcitrance, organo-mineral interactions and physical protection.

<sup>10</sup> et al.

Classifying nature helps us humans to understand it. Extraterrestrial primordial ecosystems with early soils may be billions of years away. Fortunately, there are also initial and/or curious humipedons all over our planet today. They have been described as Para humus systems; in the present work we will add 7 new Para systems to the 6 published in 2017.

A) Already described humipedons (<https://doi.org/10.1016/j.apsoil.2017.09.043>):

1. Crusto: soil crusts made by fungi, cyanobacteria, algae, lichens and other microorganisms
2. Bryo: made by mosses and lichens and microorganisms
3. Rhizo: made by root systems and microorganisms in aerated humipedons
4. Archaeo: made by microorganisms of acidic environments, or of high temperature or pressure
5. Anaero: made by microorganisms and animals in river, lake and marine shore and bottoms
6. Ligno: made by animals and fungi that feed on wood and microorganisms

B) New humipedons:

7. Abio: abiotic humipedons (living organisms of all types including viruses: absent; organic matter: possible), mineral substrate modified by abiotic factors. Ex. on the moon, mars, meteorites
8. Into: generated by the microorganisms of the digestive system of heterotrophic organisms, under the partial and involuntary physiological control of the latter
9. Filmo: made by microorganisms in thin layers, everywhere
10. Cryo: made by microorganisms and animals of frozen environments, snow, permafrost, glaciers, etc.
11. Litho: rocky debris and dust colonized by microorganisms, generally on/in the screes at the base of the rocky walls of the mountains and other similar environments
12. Mangro: made by root systems and microorganisms in semiterrestrial environment
13. Fireo: microorganisms and animals in burned organic and organo-mineral matter (Fig. 1).

Extending Para classes to include these early stages of soil formation will be useful and fun. These are the microorganisms that were the first to colonise our planet surface in strange extreme conditions. Such new settlement did not only happen about 2 billion years ago, it still happens when new surfaces are revealed, such as after rockfall or volcanic eruption – or after an industrial area becomes abandoned.

##### DESORPTION HYSTERESIS TESTING IS IMPORTANT IN SOIL SORPTION EXPERIMENTS

M BORISOVER

Institute of Soil, Water and Environmental Sciences, ARO, RISHON LEZION, ISRAEL

Sorption of inorganic and organic compounds onto soil controls the environmental fate of chemicals. Desorption and sorption isotherms determined in solution experiments may not coincide, producing a (commonly) non-closed hysteresis loop. Yet, the understanding of hysteresis is limited, and hardly clear recommendations are provided for experimentalists. Hence, soil sorption studies may not examine whether desorption is hysteretic. Lack of testing for hysteresis rules out an option to confidently claim on attainment of a full equilibrium. The consideration that if sorption kinetics were shown completed then, regardless of desorption hysteresis, sorption isotherms may be treated as being at equilibrium is not necessarily correct since slow sorption may be overlooked in short-term experiments. It is in particular true considering an OECD recommendation indicating that 'a period of 24 h is generally sufficient' to attain a soil sorption equilibrium and often indiscriminately referred to in the literature. The lack of inspecting for hysteresis may lead to confusion in distinguishing between the thermodynamic and kinetic factors controlling the environmental fate of chemicals, and, possibly in an inappropriate interpretation of sorption models and mechanisms. Thus, even if a demonstrated hysteresis is not fully understood, its examination is important. This presentation addresses two scenarios when the sorption-desorption hysteresis is identified, with no indications for continuing kinetics. (1) May the sorption isotherm be necessarily treated as being at equilibrium? A (negative) answer is illustrated using the recently proposed concept of gate-sorption site coupling<sup>1</sup>; the concentration-dependent accessibility of sorption sites capable of irreversible binding may lead to time-independent sorption isotherms to which equilibrium sorption models are not applicable. (2) Apparent equilibria (potentially proven by isotope exchange experiments) are reached across both sorption and desorption isotherms: such a 'true' hysteresis is quantified in thermodynamic terms using a properly computed sorption-desorption loop area<sup>2</sup>. Is the sorption isotherm suitable for environmental fate modeling? Not necessarily.

#### 8.03 133541 - Sustainable Soil Nutrient Management: Implications for Food, Environment, and Ecology

##### OPPORTUNITIES AND CHALLENGES ORGANO-MINERAL FERTILISERS CAN PLAY IN ADDRESSING AGRICULTURAL CARBON FOOTPRINT – A PERSPECTIVE

R SAKRABANI

Cranfield University, Cranfield, UNITED KINGDOM

##### Introduction

With increasing mineral fertilisers price and declining soil health, innovative solutions are needed to meet crop nutrient demands. One solution can be organo-mineral fertiliser (OMFs) as a new concept that take organic waste products and combines them with mineral fertilisers to produce a lower carbon footprint product.

The aim of this Perspective is to present an outlook on how OMFs can be considered as part of the toolbox to add the opportunities and challenges posed in tackling agricultural carbon footprint.

##### Methodology

The approach is in the form of a framework using Strength Weakness Opportunities and Threat (SWOT) which will critique how OMFs can play a role in agriculture.

##### Results and discussion

The strengths of using OMF is its potential to contribute to organic matter and increasing water holding capacity. Carbon content of the feedstocks used to formulate OMFs can be important for improving soil health. The weaknesses of using OMF can be related to traceability due to variability of feedstocks used to formulate OMFs. Variability can be determined using novel approaches such as near and mid-infrared sensors (nutrient content) and high energy sub-atomic particles such as neutron and muon (physical status). Contaminants levels of feedstocks needs to be controlled so that the final products are suitable. The opportunities for using OMF can be capitalised by technologies such as artificial intelligence, remote sensing and Internet of Things (IoT) to collate data on soil health and crop productivity. The threat is the need to assess the willingness to pay for it, due to uncertainty on its efficacy. OMF will be subject to regulatory restrictions to ensure that it is not classed as a waste and requires End-of-Waste status.

##### Conclusion

The SWOT analysis will provide a critique and set the perspective on future directions to consider OMF as an option in the toolbox to mitigate declining organic matter whilst tackling climate change, reducing carbon footprint and implementing a circular economy approach.

<sup>4</sup> Sociedad Mexicana de la Ciencia del suelo, PUEBLA, MÉXICO

The indigenous peoples who are located in the northern part of the state of Puebla, Mexico, have strengthened their knowledge about soils, by participating with the Center for Research in Agricultural Sciences (CICA) of the Benemérita Universidad Autónoma de Puebla (BUAP), in the realization of projects on the management and conservation of soils on hillsides and food production in backyard plots.

These projects have been funded by government agencies through different calls for proposals during the last 10 years (2006-2016). The communities are located within the Totonaca region of the state and are dedicated to the planting of self-consumption products on soils with slopes of 35%, which has led to an increase in erosion and is classified as severe. The proposal began with the establishment of stone barriers and green barriers with Vetiver (*Chrysopogon zizanioides*). The groups were made up of men (35%) and (65%) women in the community of Huehuetla and in the community of Lipuntahuaca, men (53%) and (47%) women.

The construction of living and stone barriers was achieved in 8 plots of the inhabitants and the establishment of 6 productive gardens in the plots in each community. The work was added to the incorporation of children and young people that allowed to increase the information, generating 12 training courses on the topics carried out. We continue to visit the sites through other projects and we observe a 73% maintenance in the works of the barriers, the rest suffered a change of land use, mostly for residential use. In the case of the orchards, it is observed that they have been maintained and increased by other villagers who have seen their benefits.

Improving the rigor of soil science for sustainable agriculture includes promoting equity and inclusion of scientists from the global south. This is an on-going journey. There have been many bumps along the way in efforts to improve the relevance of applied soil science and management through including all voices, especially those who have been marginalized. Participatory action research is one approach that holds out promise for soil science that makes a difference in agricultural development, and the presentation will draw on experiences in Malawi. In addition, an inclusive, positive environment is important. Mentorship programs, learning from pioneers and appropriate performance assessment guidelines are efforts at CIMMYT's program, including the "Catalysts of Change" promoting gender, equity and social inclusion (GESI) in the crop and soil sciences. Decolonizing research requires both internal reflection, and building strong partnerships with national agricultural research systems and universities. Audience participation and discussion.

**Keywords:** participatory,mentorship,Gender (GESI),pioneer,decolonial

During this presentation, we will officially launch Impact4Soil, developed as part of the ORCaSa Horizon Europe project. It is the dedicated worldwide knowledge platform to address the critical challenges of soil carbon within the "Soil Carbon International Research Consortium". Impact4Soil is a science-based, aggregative and cooperative platform designed to meet the needs of scientists, practitioners, farmers and foresters, policymakers and funders from all over the world.

We apply scientific standards to verify, gather and share trustful information.

The platform will feature 5 services:

- Geospatial data
- Scientific evidence
- Network (of projects, initiatives, research institutions...)
- Practices
- Datasets

This will enabling users to :

- Access geographical information to increase transparency on historical, current and future trends of soil carbon stocks at different spatial scales,
- Access aggregated and up-to-date scientific data to make decisions,
- Access and contribute to aggregated and up-to-date scientific data on the impact of practices on soil carbon,
- Access to consolidated, quality-assessed and reusable data,
- Sharing and discovering practices and soil carbon management experiments,
- Have an up-to-date view of ongoing efforts to manage current soil carbon stocks,
- Develop their networks.

Impact4Soil will thus contribute to the involvement of soil scientists from all regions. It will facilitate knowledge exchange and collaboration among scientists from different regions, enabling collective efforts to address global soil challenges while respecting local contexts.

#### FARMING WITH CARE - THE CASE OF HOME GARDENS IN MYANMAR

N LOPEZ

The University of Edinburgh, Edinburgh, UNITED KINGDOM

In a time of anthropogenic climate change, agriculture has become a major focus for deconstruction among feminists. New questions are being posed about how global agriculture might be practised otherwise, while growing sufficient food in a manner that replenishes the soil, the planet and its climate. In the past decade soils have been placed at the heart of agricultural transitions and soil care practices in farming have been identified as the determinants towards achieving a regenerative agriculture. Feminist political ecologists draw the attention to gendered and racialized processes within the politics of environmental degradation and the neo-liberalization of agriculture. This work explores the different soil care practices that take place among different agricultural actors in the context of sustainability transitions in Myanmar. Drawing on Feminist Political Ecologies (FPE) I untangle the kinds of caring practices that are validated and allowed to take place through the neoliberalization of agriculture in Myanmar investigating women's everyday practices in home gardens and farm fields as well as emerging organic farmers. I examine how ethnic minority women experience the current sustainability transitions and how increased agricultural changes and choices restrict and constrain their soil care practices in home gardens and beyond through the case study of indigenous women's home gardens in the Shan mountains of Myanmar. On the one hand, this analysis highlights the importance of thinking through the tensions between reproductive and productive binaries in agriculture and how those binaries invisibilise the practice of home gardens and the potential they offer to envisage diverse ways of farming and regenerative agriculture. On the other hand, together with care ethicists, I stress the necessity to think of care that considers humans and the more-than-human world in the ecological economics of agriculture. This work concludes that the marginalization and invisibility of reciprocal care practices among women is rendering alternative food projects such as home gardens less important and capable of transformative change towards a more regenerative agriculture.

<sup>4</sup> Stellenbosch, Stellenbosch, SOUTH AFRICA

<sup>5</sup> Durham, Durham, UNITED KINGDOM

<sup>6</sup> Oulu, Oulu, FINLAND

In the EU, 2/3 of soils are degraded. Soil degradation has happened because we have been treating soil as inanimate. Soil is living and it is the microbiota that is the bridge between the macro-organisms (plants and animals) and the climate, building and keeping soils healthy by literally gluing together mineral particles and recycling nutrients. Just like us and our gut microbiome, the soil microbiome needs energy and materials to stay alive and to keep maintaining and restoring soil structure to provide the ecosystem services essential for all terrestrial life. Collaborating with the soil microbiota will help us deliver net zero (SDG13), net biodiversity gain (SDG15) and to improve both human (SDG6) and planetary health.

But we are killing soil. Partly because many of the carbon and mineral rich materials that are food for the soil microbiome are not returned to soil. And partly because there is a lack of access to financial resources or capital and governance structures for women in many societies. This talk explores using more feminist approaches to soil health, and focuses on how we can work with society to benefit from partnering with soil as a living material rather than treating soil as an inanimate matrix in the crop production line. We discuss how our education system needs to change so that society can learn that soil, like people, needs feeding. The role of caring is one that is largely assigned to women, and is often resisted in typically male-dominated fields like farming, soil science and agronomic infrastructure development. A more feminist approach inherently involves inviting concepts like emotion, risk, desire and individual, case-by-case discernment, as opposed to post-industrialisation formulaic, one-size-fits-all agronomic and policy approaches. A benefit of utilising a relational, feminist approach is that it can illuminate why fulfilling our obligations to rebuild soil health are integral to addressing structural inequalities and injustices in our environmental, economic, and social relations.

#### WHY DOES GENDER MATTER TO THE TRANSITION TOWARD SOIL HEALTH MANAGEMENT?

W ZHANG, [U HETTIARACHCHI](#)

International Food Policy Research Institute, Washington DC, USA

Healthy soils play a critical role in supporting agricultural productivity, climate change mitigation and resilience, and a range of ecosystem services. Degraded and poorly responsive soils cover large areas of Africa and represent the majority of poor farmers' fields in certain regions. While many technical options for soil improvement or restoration sit 'on the shelf', there are many sociocultural, institutional, economic, and policy barriers hindering their adoption at large scale. Gender inequality is deeply embedded in and reinforces these barriers, and represents a wicked problem requiring context – and culture-specific understandings and approaches. This study builds on a conceptual framework proposed by Zhang et al. ("Soil health and gender: why and how to identify the linkages", International Journal of Agricultural Sustainability, 2021). The conceptual framework helps illuminate important gender considerations for soil health management and highlights how a range of separate and joint assets held by men and women in households, and the intrahousehold distribution of use, management, fructus, and alienation rights shape the management practices that contribute to, or undermine, soil health. These considerations are essential for identifying gender-based constraints, opportunities, and unintended consequences in promoting soil management technologies. Applying the framework, we review the empirical literature on quantitative studies of the effects of gender on soil health-related practices, decision-making (at intra-household and other relevant levels), and outcomes, and conduct a meta-analysis to shed light on the magnitude of the gender gap in the space of soil health and sustainable land/soil management. We consider both the gender of household heads and the gender of plot manager or decision-maker, although empirical studies on the latter are scant due to the lack of plot-level gender disaggregated data. Based on the meta-analysis results, we make the attempt to quantify the cost of the gender gap in soil health to the economy and call for greater investment in research and programs that empower men and women to become more effective soil health stewards.

#### POWER DYNAMICS, GENDER RELATIONS AND INTERSECTIONALITY WITHIN REGENERATIVE AGRICULTURE IN THE U.K.

C.CHANDLER, L FORSYTHE, L BÜCHI

Natural Resources Institute, University of Greenwich, Chatham, UNITED KINGDOM

This presentation will apply a critical gender and intersectional lens to regenerative agriculture (RA) in the UK, using results from a mapping of RA actors and their relative power and positionality. It will highlight relationships and power dynamics between actors, critically assess how they are shaping the national conversation around RA and soil health, consider who is excluded, and analyse how this influences RA practices and outcomes from a social and environmental justice point of view.

A 2010 study by academics at Cranfield University estimated that soil degradation was costing the British economy £1.2 billion per year. The UK government's 25 Year Environment Plan includes a focus on addressing concerns around soil health, with the stated goal of managing England's soils sustainably by 2030.

One increasingly popular approach to improving soil health in the U.K. is the concept of regenerative farming. While there is no formal agreed definition of RA, a focus on soil restoration – through methods such as mob grazing, a reduction in synthetic inputs and minimal soil disturbance – is central to most regenerative approaches. RA has attracted vocal support from a broad spectrum of actors, ranging from individual smallholders and tenant farmers through to NGOs, policymakers, large landowners and international food companies.

The relative power dynamics between actors may be having an outsize impact on how regenerative agriculture is understood and the types of support (both political and financial) that are being provided as part of the post-brexite agricultural transition. Those already disadvantaged due to gender, class, ethnicity, immigration status, sexual orientation and other forms of discrimination, in particular, may find themselves being overlooked, silenced, self excluding or negatively impacted within these policy discussions.

It is hoped that this research will provide a starting point for broader discussions about who is – and who ought to be – represented in ongoing attempts to identify, understand and support efforts to battle soil degradation in UK agriculture.

#### LIVELIHOODS DIVERSIFICATION AT WHAT COST: IMPACTS OF LAND RENTALS ON ETHNIC MINORITY LIVELIHOODS IN NORTHERN UPLAND VIETNAM

J PO

University of Greenwich - Natural Resources Institute, CHATHAM MARITIME, KENT, UNITED KINGDOM

Generations of ethnic minority communities have created and maintained rice terraces to control the downward flow of water in mountainous regions of northern Vietnam. The sub-tropical region has attracted a sharp rise in land rentals for 'hi-tech' agriculture for commodities: flowers and vegetables. The provincial government of Lào Cai approved the development of lily and rose farms in three communes since 2018. This study explores the impacts of land rental arrangements on the natural resource base and the rural livelihoods of Hmong and Yao ethnic minorities. Adopting a feminist care ethics and sustainable rural livelihoods approach, the author analysed in-depth interviews with 14 Hmong and Yao farmers from 2018 to 2019.

The paper explores the experiences of semi-subsistence farmers that are led into five-year lease agreements with a hi-tech agricultural enterprise. In an effort to diversify their livelihoods, ethnic minority households find themselves coping with land trades within an existing context of tourism boom, women working as trek guides, and distrusts between marginalized ethnic communities and ethnic majority group, which dominates the business and public sectors. Notable findings include residents being paid lease fees equivalent to the market value of rice produced on their farms instead of land market prices due to existing system of land governance. Others reported a physical pressure to enter into rental agreements as their parcels are surrounded by neighbours' parcels allocated for flower production, effectively cutting access to water for rice cultivation.

Common concerns on the lack of regulations on chemical inputs for non-food crops, decreasing soil fertility, and public health in the commune, with the fear of eventual depletion of soils when the horticultural boom ends. Residents' accounts contrasted with the publicised advantages of hi-tech agriculture as minimizing environmental impacts. This case study features how ethnic minority households' livelihood diversification through land rentals have increased households' vulnerability to food price volatility and increased risks to sustaining their natural resource base.

<sup>8</sup> Cranfield University, British Society of Soil Science, Cranfield, UNITED KINGDOM

Issues of diversity, equity, and inclusion (DEI), including gender equity, have gained increasing recognition at the beginning of the 21st century. As an academic discipline, soil science has been late in addressing gender equity, but a number of peer-reviewed studies have been published in the last four years. This study investigated gender equity in the soil science faculty, national soil science societies, and soil leadership positions of six countries (Canada, Egypt, Mexico, Nigeria, the United Kingdom, and the United States of America) using data publicly available on the internet and from the soil science professional societies. We found that women still lag behind men among our soil science faculty by considerable margins, and that the percentage of women in soil science faculty positions are similar to those for women faculty in many other scientific fields. There are differences in gender equity by soil science subdiscipline that vary by country. However, in countries where data is available to make comparisons over time the gap has closed to some extent, both overall and for subdisciplines, over the last 6-8 years. Women also often hold leadership positions at rates that are lower than their representation among the faculty and membership in professional societies. In addition, women are less frequently recognized with high level awards such as society Fellowship awards compared with men. This study concluded that progress has been made on several fronts, particularly in the last 6-8 years, but there is still much work to be done to achieve gender equity in soil science.

##### PATHWAYS TO INCLUSIVITY: PRIORITIZING DEI RECOMMENDATIONS

S.CHAPMAN<sup>1</sup>, T.CARTER<sup>2</sup>

<sup>1</sup> Soil Science Society of America, Madison, USA

<sup>2</sup> -, Madison, USA

In a world that requires creativity, collaboration and innovation to address the issues of our changing planet, it is crucial for our Societies to reflect the values and importance of diversity, equity, and inclusion (DEI). The Soil Science Society of America, along with its sister Societies (American Society of Agronomy, Crop Science Society of America) recognized diversity, equity, and inclusion (DEI) as a top priority in recent strategic plans and acknowledge that enhancing representation within our Societies is essential to fostering strength, creativity, and innovation in our scientific fields. The program is comprehensive and all-encompassing throughout programs, processes, and systems and continuously expands as we delve into the work.

The ASA, CSSA, SSSA DEI Committee is dedicated to strengthening and diversifying the potential workforce in agricultural and environmental sciences by enhancing equity within our sciences and inclusion throughout our Societies. Our vision is to conduct our scientific and professional activities in a manner that provides a safe and welcoming environment for all participants. The committee works to address the overall Societies' DEI initiatives as informed by Members, the Boards of Directors, the elected leadership, staff, and a member survey, all leading to an approved DEI Recommendations Report.

The Recommendations from the Report are listed in priority order with the first four viewed as most important by members:

- Professional Conduct and Anti-Harassment Policies Development
- Education/Training Planning
- Mentoring Program
- Support and Collaborations Development
- Leadership, Governance, and Policies Review
- Communications Actions
- Metrics Measurements
- Internal Staff Programs

Highlights of the presentation will focus on data from the research of DEI in the Societies, the recommendations, and associated actions that have been taken to build on diversity, equity, and inclusion in SSSA, ASA, and CSSA.

##### EMPOWERING WOMEN IN SOIL SCIENCE: BRIDGING THE GENDER GAP THROUGH COMMUNICATION AND EDUCATION PROGRAMS

B ALVAREZ TORRES, T DESUTTER, L MALONE

Department of Natural Resource Sciences, North Dakota State University, Fargo, USA

A comprehensive exploration of the empowerment of women in soil science, focusing on bridging the gender gap through strategic communication and inclusive programs, is necessary. Highlighting the contributions of women in the field's history, light is shed on their historical achievements and the hurdles they have confronted. The objective delves into the pivotal role that effective communication plays in reshaping the narrative of women in soil science. Various initiatives and programs that have successfully amplified women's voices in the discipline are analyzed, including projects designed to empower women and marginalized communities in soil and other sciences by creating a supportive and inclusive ecosystem through networking events, educational initiatives, and advocacy campaigns aimed at increasing the representation of women in soil science. Through this presentation, the aim is to contribute to a more inclusive and equitable future in soil science and related fields. The findings and insights offer valuable lessons and strategies for creating a diverse and welcoming community that bridges the gender gap and empowers all individuals, regardless of their gender or background.

<sup>4</sup> School of Earth, Atmosphere and Environment, Monash University, Clayton VIC, AUSTRALIA

<sup>5</sup> United States Dept of Agriculture- Agricultural Research Service, Mandan, USA

<sup>6</sup> Federal University of Technology, Paraná, BRAZIL

Globally the importance of diversity, equity, and inclusion (DEI) in soil science has been recognized by the International Union of Soil Sciences as well as professional organizations, and universities. The growing institutionalized regulations and federal laws express the normative ethics undergirding DEI efforts in soil science, and science, technology, engineering, and mathematics (STEM) disciplines. However, gender inequality concerns, stereotyping of women and intersectionality issues are still prominent as have been reported in various recent publications. Disparate valuations of the work of men and women irrespective of productivity similarities express the double and triple-bind that women, especially women of color or from minority groups, have faced in soil science. Hegemonic masculinity theory has been proposed to perpetuate such gender inequality. Hegemonic masculinities, that have manifested in many cultures around the globe and across time are considered social and gendered constructions, involving men's domination over women and other men, often minority and underrepresented groups in society. Discursive construction and heightened uncertainty about one's place in the world and gender order open new perspectives of addressing power hierarchies in STEM and soil science. Equity-oriented actions and resource allocations lifting women and minorities up are one way to address imparities. However, the over emphasis on equity tends to create new gender, social, educational hierarchies, and social disparities. We advocate for promoting the principles of equality in the soil science profession to create work cultures with a human face with honoring social equality and justice, belonging, and care for each other. Equality embraces the ethical belief that equal treatment of people co-creates global human flourishing and a sustainable planet Earth. The United Nations Educational, Scientific and Cultural Organization has recognized that science and gender equality are essential to achieve sustainability at global scale. Strategies that create a culture of equality with a human face honor core human values through investment in pro-social and emotional development, mentoring, coaching, allyship, and human flourishing

<sup>6</sup> Texas A&M University, College Station, USA

<sup>7</sup> PBI-Gordon Corporation, Dallas, USA

<sup>8</sup> Alliance of Crop, Soil and Environmental Science Societies, Madison, USA

Mentoring is a significant tool for the personal and professional development of soil science society and institutional members. However, mentoring programs are often disconnected, member-driven with little resources, and do not have the capacity to educate and train members on effective mentoring. If approached thoughtfully, higher education and professional soil science organizations can utilize mentoring programs to create more inclusive environments that enhance equity among underrepresented groups and retention of members. In 2021, the Soil Science Society of America, along with the Agronomy Society of America and Crop Science Society of America (the Societies) released results of a Diversity, Equity, and Inclusion (DEI) membership survey in which mentorship was one of the highest ranked potential programs to enhance DEI within the Societies. Furthermore, the Societies commissioned a "Future of Membership" survey where an average of 85% of participants somewhat or strongly support the need for development of a formal mentoring program. Therefore, our overall goal is to develop a comprehensive, online, user-friendly mentoring program that connects members within and across societies and institutions. In 2023, the Societies secured funding for an online mentoring platform that will contain customizable program tracks to provide members the unique opportunity to connect on several platforms, such as within specific programs, divisions, 1-on-1, and groups (specialty groups, graduate student committees, etc.). This program contains i) MatchIQ 2.0 technology that will allow us to effectively match participants based on key traits, ii) built in training models and certifications, iii) dynamic connections plans that prompt mentors and mentees to incorporate tasks, goals, and content delivery into their discussions, iv) automation for every step of the process, if desired, enabling for a larger scale mentoring program to be ran more efficiently, and v) tracking of program metrics. This talk will discuss the development of the Societies' mentoring program and the potential impact it will have on members and creating a more inclusive environment.

#### 1.05 133836 - Preparing the Next Generation of Pedologists - Needs and Opportunities

##### CREDENTIALING – A PROPOSED PATH FOR FUTURE PEDOLOGY PROFESSIONALS

D GIBAS, L SMITH, J CUDAHY

Soil Science Society of America, Madison, USA

As times change and we consider more global needs for having an integrated soil science workforce, there is a corresponding need for understanding appropriate curricula, training, and expectations for future soil scientists and the challenges they will face. This talk will focus on initiating a discussion on how to engage, train, and provide meaningful credentials to the next generation of soil scientists. This is necessary not only in the U.S., but across geographic boundaries and on a global scale. Soil, along with water, form the basis of life by providing food across all scales of our landscapes. We need a plan to enhance recognition of the soil science discipline and its expertise of applications in biology, chemistry, physics, ecology, etc., as integral to our management of healthy soils and sustainable land use. We need to prepare future pedologists to meet that challenge and at the same time assure the general public that pedologists have the working knowledge needed to address many issues. The Soil Science Society of America has had a soil science credentialing program in place for over 30 years. It serves to provide assurances to the general public that a Certified Soil Scientists have required education, experience, and knowledge to perform soils related work. There are others that also have credentialing programs related to soil. Experience from existing credentialing programs could be used to develop a global credential for future pedologists that is meaningful globally and provides recognition for those who have the relevant knowledge, experience, and qualifications to make recommendations regarding our soil resources.

<sup>9</sup> Ontario Ministry of Agriculture, Food and Rural Affairs, Guelph, CANADA

As Canada is located within temperate and polar latitudes, global warming is projected to result in substantial changes to temperature and precipitation patterns across Canada's vast ecoregions. This will require ongoing adaptation to the evolving nature and functionality of soils in both managed and natural ecosystems. The intensification of land management, notably for precision agriculture, made possible by technological innovations, is driving demand for relevant interpretative information, derived through proximal and remote sensing, with respect to reference profile information. In Canada, as elsewhere, dedicated soil science programs are frequently being incorporated into broader programs, often resulting in a progressive loss of disciplinary expertise, as well as the ability to attract critical numbers of students to sustain advanced level disciplinary courses. Moreover, as universities struggle with budgetary shortfalls, practical training (e.g., laboratory and field courses) is often sacrificed. At the same time, there is an increasing need to provide effective linkage to allied sciences, such as geology, hydrology and botany. On the other hand, the rapid evolution of virtual technologies presents opportunities for national inter-institutional strategies to maintaining the capacity to deliver rigorous education. Finally, evolving generational career expectations continue to present challenges to the practice of soil science in both public and private sectors, as 'desk' jobs are often preferred over 'in-field' jobs. This presentation will provide a snapshot of the pedology in Canada, and strategies being employed to address the evolving needs of practicing professionals.

##### IT'S GETTING HOT IN HERE – GLOBAL WARMING AND THE SOIL OF MOUNTAIN NORWAY SPRUCE STANDS

D. KUPKA<sup>1</sup>, J. OLIWA<sup>2</sup>, P. GRUBA<sup>1</sup>

<sup>1</sup> University of Agriculture in Krakow, Faculty of Forestry, Department of Forest Ecology and Silviculture, Krakow, POLAND

<sup>2</sup> University of the National Education Commission, Institute of Biology and Earth Sciences, Krakow, POLAND

Global climate change is threatening the sustainability of forest ecosystems. The observed increase in atmospheric temperature has been unparalleled in the past two thousand years. In temperate zone, Norway spruce is a species particularly sensitive to changing environmental conditions. The process of spruce decay in mountain areas has been observed for several decades, but little attention has been paid to the relationship between climate warming and the topsoil in spruce stands. Also, little is known about future scenarios for changing the species composition of these stands. The aim of the presentation is to present the results of two climate experiments during which warming was simulated in situ. The research, based on the artificial 0.5 °C soil warming, was carried out in the Western Carpathians. Results showed a significant effect of warming on the chemistry of the topsoil and ground vegetation. Warming caused a decrease in the content of total and labile forms of carbon and nitrogen in the soil, as well as total phosphorus, proving faster mineralization of soil organic matter. A significant increase in the content of ammonium in the warming soil was observed, which was the prime reason for the significant increase in the pH of the warming soil. The increase in soil pH under warming was related to a decrease in the strength of organic acids and an increase in the proportion of aluminum in the sorption complex. The aboveground parts of ground vegetation subjected to warming were characterized by increased leaf carbon content. Warming also had a different impact on the photosynthetic activity and pigment composition of the leaves of the young generation of beeches and spruces, which suggested a diverse acclimation potential of these species. The observed symptoms of changing habitat conditions will negatively affect the health of spruce stands. The results obtained can serve as a basis for silvicultural planning in mountainous areas where Norway spruce is still the dominant species.

##### ORIGIN, PROPERTIES AND TRANSFORMATIONS OF SOIL LAMELLAE - A CASE STUDY FROM SOUTHERN POLAND

M. GUS-STOLARCZYK

Jagiellonian University, Institute of Geography and Spatial Management, Department of Pedology and Soil Geography, Cracow, POLAND

Lamellae are morphological illuvial forms containing an ordered clay fraction on mineral grains, and increased content of iron and aluminum oxides and soil organic matter. Over the years, lamellae have been the subject of research in various fields, including paleogeography, sedimentology, geomorphology, and soil science. They are commonly found in soils formed from Quaternary deposits. The mechanisms of lamellae formation have been mainly described in soils developed from sandy materials of various origins; however, detailed studies on lamellae in loess soils are rare.

The aim of the study was to determine the origin, properties and transformation of lamellae in soils formed from sandy and silty parent materials, subjected to various soil-forming processes.

The studied soils from southern Poland were described and sampled. A detailed description of lamellae morphology has been included. Physical and chemical analyses, including texture, mineral and chemical composition, total carbon content, and concentration of pedogenic forms of iron and aluminum, as well as micromorphological studies, were conducted. The studied soils were classified according to the WRB system.

Lamellae are formed due to the illuviation of clay fraction, emphasizing the key role of pedogenesis in their formation. In soils developed from loess, lamellae form as a result of clay translocation, initiated after the decalcification of the upper soil parts. Conversely, characteristics of sandy parent material determine the redistribution and accumulation of pedogenic forms of iron and aluminum, clay fraction, and soil organic matter, playing a crucial role in the pedo-petrogenic origin of lamellae in sandy soils.

The transformations of soil lamellae can be categorized based on the direction of change, either towards the degradation of lamellae – caused by processes such as bioturbation, swelling and shrinking, eluviation, and chemical dissolution of iron compounds – or towards the enhancement of lamellae expression. The latter occurs gradually through the illuviation of clay fraction and iron compounds.

The research was financed by the National Science Centre in Poland (Grant No. 2018/29/N/ST10/00398).

##### FROM SOIL TO WATER - PATHS OF SOM TRANSFORMATION WITHIN MOUNTAIN PEATLAND SOILS DUE TO DRAINAGE ON THE EXAMPLE OF THE WESTERN BIESZCZADY MOUNTAINS

M. STOLARCZYK

Institute of Geography and Spatial Management, Jagiellonian University, Kraków, POLAND

Specific examples among mountain peatlands are those related to ombrogenic conditions which are highly sensitive to changes in the environment. One of the most important research issues addressed in the functioning of peatland ecosystems and organic soils related to peatland drainage is the phenomenon of releasing water-soluble organic matter and nitrogen compounds into surface waters. Ombrogenic peat soils occurring in mountainous areas are often overlooked in global analyses concerning carbon sequestration and the storage of biogenic compounds.

Therefore, the aim of the presented research was to determine the potential release of dissolved organic matter and nitrogen compounds from organic soils characterized by varying degrees of transformation. An attempt was also made to compare the molecular composition of organic matter in the solid phase of soil, dissolved in the soil solution, and circulating in the waters within the peatland.

The organic soils selected for the study were located in three ombrogenic peatlands in the Upper San River Valley (Eastern Carpathians Mts.). The main characteristic distinguishing these sites and consequently, the soils, is the impact of human activity. The drainage of peatlands dating back to the 19th century have led to noticeable contemporary changes in the morphology and properties, mainly of the surface horizons. Differences between the studied soils resulting from the degree of transformation are clearly evident in soil pH, degree of organic matter decomposition and mineral nitrogen transformations. The higher advancement of organic matter transformations caused by progressing mineralization with increasing peatland transformation degree, which is primarily demonstrated by the narrowing of the C/N ratio and the decrease in organic carbon concentration, does not result in an increase in dissolved organic matter towards more drained soils. Additionally, it was observed that the organic matter released into the soil solution and groundwater is characterized by a different molecular composition than the one originally accumulated in the examined organic soils.

##### **GLOMUS MACROCARPUM ASSOCIATED WITH GRASSES OF THE GENUS AXONOPUS P. BEAUV. IN AREAS OF PRESERVED CERRADO**

L DE OLIVEIRA BRASILEIRO, [A MONTEIRO DE PAULA](#), D F SALAS MENDES, J GALBA BULSATO

University of Brasilia - Faculty of Agronomy and Veterinary Medicine, Brasilia, BRAZIL

Arbuscular mycorrhizal fungi (AMF) enhance plant development, especially in adverse conditions. However, little is known about the presence of these microorganisms associated with native grasses of the Brazilian Cerrado biome under natural conditions. The present work aimed to evaluate the presence of AMF in grasses of the genus *Axonopus* P. Beauv. in two areas of the Federal District characterized as fragments of Cerrado, aiming to subsidize future work on the recovery of degraded areas in the central region of the Cerrado. For this purpose, the roots and adjacent soil were collected to evaluate the rate of mycorrhizal colonization and the abundance of AMF spores. Subsequently, some AMF species were identified based on morphological aspects of the spores. The highest colonization rate was observed in the *Axonopus* sp. (95%) and the lowest value for the *Axonopus aureus* sample (59%). The average density of AMF was 9 spores g<sup>-1</sup> soil in the Bernardo Sayão Ecological Park, and 12 spores g<sup>-1</sup> soil in APA Paranoá in 2017. (Seventeen) 17 species of AMF were identified, with *Glomus macrocarpum* being the predominant species comprising more than 71% of the total spores in the *Axonopus* species studied. It is concluded that AMFs are strongly associated with grasses of the genus *Axonopus*, with their symbiotic relationship with the species *Glomus macrocarpum* having high potential in plans that aim to adopt microbiological tools as a basis for the recovery of degraded areas.

**Keywords:** Spore diversity, Mycorrhizal colonization, Area recovery, Drought stress, Native grasses

##### ANALYSIS OF AGRICULTURAL EMISSIONS OF NITROUS OXIDE AND CULTIVABLE AREA IN MÉXICO

V.M. MONTOYA JASSO <sup>1</sup>, M.E. RAMÍREZ GUZMAN <sup>1</sup>, J.M. ARREOLA NAVA <sup>2</sup>, A.L. GONZÁLEZ SERRANO <sup>3</sup>, J.M. ARREOLA TOSTADO <sup>2</sup>, D. LARIGAUDIERE <sup>4</sup>, L.R. PESQUERA <sup>4</sup>, R. ..Y. LEGUIZAMO FLORES <sup>2</sup>

<sup>1</sup> Colegio de Postgraduados. Edafología., Texcoco, MEXICO

<sup>2</sup> Consultor agrícola. Privado, MEXICO

<sup>3</sup> Universidad de Guanajuato. Ciencias biológicas, MEXICO

<sup>4</sup> SAFMEX S.A. de C.V. Desarrollo agrícola, MEXICO

In comparison to reports prior to the Industrial Revolution, the current concentration of nitrous oxide (N<sub>2</sub>O) has increased by approximately 20%, with the agricultural sector being the most representative source, contributing to 50.4% of total gas emissions due to the excessive use of nitrogenous fertilizers. However, the land allocated to the agricultural sector in México has been decreasing each year in response to the development of infrastructure and housing, coupled with the abandonment of agricultural activities due to climate effects, safety concerns, and ongoing uncertainty regarding the profitability of small and medium-scale production systems. The objective was to analyze the impact of the reduction in agricultural land in México and its effect on agricultural N<sub>2</sub>O emissions. To achieve this goal, historical data on N<sub>2</sub>O agricultural emissions in thousands of metric tons (TMM) and hectares of land dedicated to agriculture in México from 1965 to 2021 were obtained. Subsequently, an autoregressive integrated moving average (ARIMA) model was applied to both series, followed by an intervention analysis on the N<sub>2</sub>O emissions series. An ARIMA (1,1,0) model was employed for series analysis, revealing an annual deterministic trend  $yt-1$  of 763.30 TMM of N<sub>2</sub>O, even when, starting from 2007, there was an annual average reduction of 7.5 million hectares dedicated to agriculture. The intervention model identified six outliers: 1997, 1998, 1999, 2000, 2017, and 2018, corresponding to years with the greatest impact on the reduction of N<sub>2</sub>O emissions, aligning with México's inclusion in national and international environmental treaties, as well as the increase in agricultural input costs. The area allocated to food production in México has significantly decreased without observing significant decreases in N<sub>2</sub>O emissions from agriculture.

##### REPRESENTATIVENESS OF ORGANIC MATTER IN THE PHYSICAL QUALITY OF SOILS UNDER INTENSIVE TILLAGE

V.M. MONTOYA JASSO <sup>1</sup>, V.M. ORDAZ CHAPARRO <sup>1</sup>, G.S. BENEDICTO VALDES <sup>1</sup>, E.V. GUTIERREZ CASTORENA <sup>2</sup>, J.M. ARREOLA TOSTADO <sup>3</sup>

<sup>1</sup> Colegio de Postgraduados. Edafología., Texcoco, MÉXICO

<sup>2</sup> Universidad Autonoma de Nuevo Leon, Nuevo Leon, MÉXICO

<sup>3</sup> Consultor Agrícola, Celaya, MÉXICO

Intensive agricultural management results in alteration of soil, causing a decrease in quality and physical fertility. Physical properties of soil, as well as the content of organic matter, influence to generate indices of physical quality of soil and evaluate effects on crop production. The objective was to evaluate the physical quality index of soils exposed to frequent changes in their characteristics due to intensive tillage effects. Unaltered samples from five vertisols from Acámbaro, Guanajuato, México, were used; these soils were put through a comprehensive characterization of physical properties, as well as the determination of organic matter content. To understand the impact of the absence of organic materials in the soil, organic matter was removed using 30% hydrogen peroxide and compared with soils from which the organic materials were not removed. Principal component analysis was applied using SAS® statistical software to obtain the representativeness of the model variables and to obtain the degradation index and subsequently generate soil physical quality indexes. One soil (S4) with a low degradation index was found, a result of particle stability due to the aggregation effects favored by its high organic matter content (6.83%). The remaining soils (S1, S2, S3, and S5) obtained a high degradation index, reflecting that the constant tillage intensity to which the soil has been subjected for crop production. The physical quality index of all soils was low when the organic matter was removed, showing that high physical quality indexes in soils appear with the presence of organic materials, ensuring a favorable physical condition for crop growth and development. The contribution of organic matter in intensive agriculture improves the physical quality index over a considerable period of time, positively impacting soil conservation.

##### USE OF UNITED STATES MID-INFRARED MODELS FOR SOIL ORGANIC CARBON PREDICTION IN HAITI

M. DORANTES, B. FUENTES, D. MILLER

University of Arkansas - Department of Crop, Soil, and Environmental Sciences, Fayetteville, USA

Soil organic carbon data can inform management for soil functions, agricultural productivity, and soil security, but current measurement methods can be expensive. Large mid-infrared soil spectral libraries, such as that curated by the USDA, provide an opportunity to build robust calibration models that can be used to predict organic carbon in new areas like Haiti. However, appropriate selection of calibration sets is required. The objective of this study was to evaluate the effectiveness of pedologic criteria and spiking to construct a calibration model from a United States mid-infrared soil spectral library (i.e., general library) that would accurately predict organic carbon content in the Cul de Sac region of Haiti (i.e., target area). Eight schemes were tested to construct calibration models using a fraction of the general library to predict organic carbon in the target area. The schemes included models constructed from observations of the same soil taxonomic orders as in the target area, the same suborders, same taxonomic class in combination with a minimum carbonate content, and spiked variations of all models. Memory-based learning was used for the general library models. Additionally, a partial least squares regression was used to construct a calibration model using a random sample of target area observations. Subsetting by shared suborders (RMSE = 0.65 and 0.70%; RPIQ = 1.56 and 1.44 for the suborders and suborders plus carbonate content model, respectively) improved predictive performance over subsetting by shared orders (RMSE = 0.76 and 0.81%; RPIQ = 1.34 and 1.25 for the orders plus carbonate content and orders model, respectively). Spiking the general library calibration sets with 25 target area observations produced the most desirable and reliable predictions (RMSE: 0.28-0.33%; RPIQ: 3.16-2.72). In addition, the spiked models outperformed the target area model. Our results suggest that these optimization techniques are effective in reducing model prediction error and can be used to predict organic carbon content in new target areas using USDA's mid-infrared soil spectral library.

#### 2.02 129339 - The development of Soil Science in the IUSS countries: 100 years of history

##### THE ROOTS AND DEVELOPMENT OF CZECH SOIL SCIENCE AS AN INTEGRAL PART OF THE IUSS COMMUNITY

B. SARAPATKA

Palacky University and Czech Society of Soil Science, Olomouc, CZECH REPUBLIC

Deeper understanding of soil science began to significantly expand in the 18th century, thanks to influential persons in various countries. Agricultural institutions were established at universities during this period, including one at the University of Prague in 1776. Subsequently, especially in the 19th century, the field of soil science saw the documented contributions of numerous individuals. In the early 20th century, notable names like Josef Kopecký and Julius Stoklasa emerged, both being appointed honorary members of IUSS (ISSS) in 1924 and 1935, respectively. Notably, Prof. Kopecký excelled not only in soil physics but also in soil mapping. In 1922, he organized a Prague conference that preceded the establishment of ISSS (now IUSS) in Rome in 1924.

Following the formation of Czechoslovakia in 1918, other noteworthy persons include Prof. Novak, Dr. Spirhanzl, and Prof. Smolik. The post-World War II period saw the influence of collectivization of agriculture on Czechoslovak soil science due to the urgent need for increased food production. Consequently, soil survey and mapping gained significance, leading to the initiation of the Comprehensive Soil Survey from the early 1960s, covering 7.5 million hectares of agricultural land in Czechoslovakia.

Over time, soil science expanded into various domains, with current research results being published in international journals and applied in agricultural and forestry practices. Professors Kas, Kosil, Pelišek, and Nemeček were influential in the early post-war decades. The appointments of Professors Miroslav Kutilek and Josef Kozák as honorary members of IUSS (1998 and 2016) affirm the high academic standard maintained by Czech soil science. International collaboration and participation in the IUSS community remain crucial, with ongoing close cooperation with Slovak colleagues despite the division of Czechoslovakia into two states.

##### CONTRIBUTION OF THE GERMAN SOIL SCIENCE SOCIETY (DBG) TO ISSS/IUSS SINCE 1926

K. FEGER

TU Dresden / German Soil Science Society, Dresden, GERMANY

The German Soil Science Society (DBG) was founded in 1926 as a section of the International Soil Science Society (ISSS). In the 1930s DBG already had up to 200 members from which about the half was also members in the ISSS. Already at the very outset soil scientists from Germany had become engaged in the international cooperation of soil science as a rather young but quickly developing discipline. This applies in particular to Emil Ramann and Friedrich W. Schucht who together with David J. Hissink (Netherlands) tirelessly worked to make the foundation of the ISSS happen.

Emil Ramann (1851 - 1926) can undoubtedly be regarded as a precursor and leading pathfinder for the ISSS. Friedrich Schucht (1878 - 1941), served as President of the ISSS between 1935 and 1941. Already before WW-I he had fostered international cooperation by editing the International Reports on Pedology which appeared until 1924 - even during the time of WW-I. Thereafter until his death in 1941, Schucht was in charge of the Proceedings of the ISSS, the society's central organ which appeared together with Soil Research as its supplement in the three publication languages English, French and German. WW-II shattered all plans for the fourth ISSS Congress which was foreseen to be held in 1940 in Heidelberg. Hermann Stremme (1879 - 1961), G.A. Krauss (1888 - 1968), and E.A. Mitscherlich (1874 - 1956) significantly contributed to ISSS activities. The Nazi takeover in 1933 also affected the DBG and its relationship to ISSS. After the end of the terrible war and collapse of the Nazi regime the DBG like other scientific associations in Germany was dissolved. The re-establishment took place in 1949. Thankfully, rather soon the international isolation could be overcome. Karl H. Hartge was President of the ISSS (1982 - 1986) and organizer of the 13. World Soil Congress 1986 in Hamburg. Rainer Horn served as IUSS President during the period 2015 - 2016.

##### SOIL AND LAND RESOURCES RESEARCH IN EAST AFRICA: A HISTORICAL PERSPECTIVE

D.N. KIMARO <sup>1</sup>, O.D. KIMARO <sup>1,4</sup>, M. ISABIRYE <sup>2</sup>, M. KIFUKO-KOECH <sup>3</sup>, K.H. FEGER <sup>4</sup>

<sup>1</sup> Department of Agriculture, Earth & Environmental Sciences, Mwenge Catholic University, Moshi, TANZANIA

<sup>2</sup> Faculty of Natural Resources and Environmental Sciences, Busitema University, Tororo, UGANDA

<sup>3</sup> Kenya Agricultural and Livestock Research Organization (KALRO), Food Crops Research Institute Kitale, Kitale, KENYA

<sup>4</sup> TU Dresden, Institute of Soil Science and Site Ecology, Tharandt, GERMANY

The Soil Science Society of East Africa (SSSEA) at its inception in 1974 continued to recognize the importance of soils and devoted its focus and dedication to advancing knowledge, and devising management practices with scientific evidence to manage, conserve and sustain soil functions and services in agriculture, general environment with a focus on the ecosystem and landscape (watershed). The Society continued to promote the study, research, teaching and application of soil science and related subjects and disciplines in East Africa. Some of the major activities carried out over the lifespan of SSSEA include surveying and mapping of soil and land resources, Integrated Soil Fertility Management (ISFM), and soil and water conservation.

Soil research in East Africa dates back to early activities during colonial times. The Provisional Soil Map of East Africa from 1937 is based on the Catena concept (G. Milne, 1898–1942). Before WW-I, the German Paul Vageler (1882-1963) had undertaken a pioneering soil survey which can be seen as a precursor of Milne's Catena concept. Early soil science development in Tanzania also included soil fertility and soil testing research centers, most of which are still operational to date.

In Uganda, a committee formed already in 1910 conducted a series of detailed soil surveys to examine the effects of various farming systems on soil fertility and crop production. In 1958/61 a soil map of Uganda was produced at the scale of 1:250,000. In Kenya, knowledge of soil was promoted in 1926 by motivating the public to participate in soil analysis through the publication of hints on collecting soil samples and soil mapping. Most of the soil works during the pre-war period, concentrated in coffee-growing areas. The post WW-II years manifested the resumption of soil and land resource surveys. This was mainly in connection with the development of new land for African settlements but later extended to detailed surveys for irrigation, sugarcane development, and improved land use.

#### BURIED CLOTH TECHNIQUE: SOIL MICROBIAL ART AS A TEACHING TOOL FOR LABORATORIES

J. IBBINI<sup>1</sup>, R. JANKE<sup>1</sup>

<sup>1</sup> Hashemite University/Department of Land Management and Environment, Zarqa, JORDAN

<sup>2</sup> Sultan Qaboos University/ Department of Plant Science, Masqat, OMAN

Soil, the hidden, frontier; these are the voyages of the soil fabric-ship, with a continuing mission to explore new worlds, seek new life forms, meet new communities, and receive communication signals from the most ancient life forms, where no one has gone before.

This modified quotation from Star Trek: Enterprise is usually the opening of my soil art laboratory. This is where I explain to my soil microbiology students how we can visually see the effect of the soil microbial community on the fabric after burying a piece in the soil for at least one month. The buried cloth technique can be used to compare activity of soil with different amendments and different conditions. Any variation in the soil environment can lead to a shift in the microbial community creating different colors and patterns on the fabric. The microbial art is then correlated to the activity of the soil microbial community. Exploring the soil structure and the minute universe of interactions among air, water and minerals leads to a better understanding the soil microhabitats affecting the life forms in that ecosystem.

In this oral presentation, we will illustrate how the buried cloth technique has been used in our classrooms, and how it can be a simple tool for teachers and soil scientists to assess the soil microbial activity. Results obtained in this visually allow them to record observations and describe what factors were more effective in controlling the microbial activities. Photographs are taken of the fabric pieces and digitally used for educational purposes. This initiative aims to cross link the fields of soil biology, physics and chemistry. Moreover, the learning lessons collected from the microbial art pieces symbiotically weave the relationship between art and science. This intricate relationship seems to be gaining more attention from educators, where art is adding a new dimension to science and technology, and science can become more of a personal relationship through art.

#### ANIMATING SOIL HEALTH: BREATHING LIFE INTO SOIL, CAMPAIGNING THROUGH STOPMOTION FILM

J. PEARL

Ecoartspace, Santa Fe, USA

Our visual understanding that soil is healthy is generally gathered by reading how green a landscape is, how lush the plants growing there are. There is little understanding in the general public that soil is a highly complex biome. Making the invisible, visible is one of the artist's key roles in society, including what may be hiding in plain sight: like the awe-inspiring biodiversity in healthy soil.

In this multidisciplinary session, artist Jo Pearl (UK) will share two short films about soil health and discuss methods for creating environmentally-charged, stop-frame animations.

In her project 'Unearthed,' Pearl draws the viewer's perspective down to examine the choreography of ever-more tiny beings that inhabit the soil through material-rich, claymation. Pearl will also present a short collage animation by Cindy Stockton Moore (USA) titled 'Urban Refuge' a playful soil portrait of John Heinz Natural Refuge in Philadelphia that combines chromatography, buried cloth experiments and extracted DNA data analysis with hand-drawn animation.

After the short screenings [with a combined running time of 8 minutes] the artist will discuss the potential of art activism to change mindsets about soil: by bringing ideas to life, revealing hidden beauty, and catching audiences off guard.

The time-intensive process of animation, slowly breaking down and building up imagery, is an apt metaphor for how healthy soil is created. While taking different approaches, both artists use cinematic arts to take a closer look at the organisms thriving underground - engaging connections between the human and more-than-human world.

This session asks: When nature can be off-putting and statistics too dry, how can we enchant a germaphobic, modern audience about soil? How can we invite them to appreciate that the ground beneath our feet is a secret world of breath-taking biodiversity, with mysterious agency and a treasure trove of solutions to the climate crisis? Does animation have a special role to play in bringing the subject to life?

#### A BRIEF HISTORY OF THE “BURIED COTTON CLOTH ASSAY” USE IN SCIENCE AND ART AND CURRENT COMPARISONS OF DIVERSE SITES USING METAGENOMIC INDICATORS

R. JANKE

Kansas State University Dept. of Horticulture, Manhattan, USA

The “buried cloth” technique received significant interest in the 1980s among soil scientists and biologists seeking new ways to evaluate soil and environmental quality, though the original use of the method can be traced to 1947. Ecologists have historically used bags of plant materials in “litter bag studies” where the rate of decomposition could be quantified, but the use of cotton offers a new way to standardize the test. Currently, artists, researchers, and farmers are using it as both a quantitative and a qualitative, visual method to measure the rate of decomposition caused by bacteria, fungi, and other soil creatures that feed on cellulose. In some cases, the results correlate with soil carbon, and in other cases, with soil nutrient levels – with higher levels resulting in more decomposition. A more difficult task is to determine which species of microbes are responsible for the decomposition. Prior to the use of metagenomic identification tools, 99% of soil microbes were unculturable, and little is known about them. I have used the buried cloth method to illustrate the importance of soil quality to students and farmers, along with soil nutrient testing. In collaboration with fellow art students at Goddard College, we documented participants’ experiences regarding the process of burying and then digging up the cloth. Later, we created a site-specific public art installation, to document the biological activity of eight different soil series found at Fort Worden state park, in a project called “The Soil Remembers.” The most recent project includes multiple participants from the ecoartspace soil dialogue group, where soil quality testing and DNA (metagenomic) identification of archaea, bacteria, and fungi was performed on multiple sites across many ecosystems on two continents, in conjunction with use of the buried cloth. The process of collaboration and results will be presented to inspire future research and artistic collaborations with soil.

#### SOUND OF SOILS: TWO APPROACHES TO A MULTISENSORY UNDERSTANDING OF SOIL

A. YONCHA <sup>1</sup>, K. GOLDSMITH <sup>2</sup>

<sup>1</sup> Metropolitan State University of Denver, Denver, USA

<sup>2</sup> Ecoartspace Member, Dubbo, AUSTRALIA

K Goldsmith and A Yoncha are two artist members of the Soil Dialogues work group of Ecoartspace. In 2023-2024, they each buried cotton fabric samples underground for about a month, in Central West New South Wales Australia and Ada Oklahoma USA, respectively. This process unearthed interventions made on the fabric by the soil microbiome community, which is materialized via sound.

Goldsmith's "#SoundOfSoils" project puts an ear on the tenuous, rudimentary soils of Central West New South Wales, capturing an intimate, reciprocal conversation between the artist and these 'good-for-nothing' soils. Seventy per cent of soils in Australia are considered unproductive because they are arid or semi-arid. However, these ancient soils have supported an ecosystem of native Australian flora and fauna for hundreds of thousands of years.

"#SoundOfSoils" celebrates ancient earthy sands and their value to more-than-human life in a rapidly changing climate. Goldsmith captures the initial silence of the soils at burial through to an increasing range of clicks, rasps, crackles, munches and rustling as the subterranean world comes to life, clearly demonstrating how the ecosystems depending on these soils have adapted to extreme conditions.

Yoncha's "Cross-timbers" project draws from non-traditional, music notation. The unearthed fabric acts as a musical score, with data isolated from her soil sample in the lab translated into sound. We hear patterns in repeated musical motifs – ratio of aerobic versus non-aerobic bacteria, ratio of gram negative versus gram positive bacteria, moving musical lines representing motile microbes, softer sounds representing rounder shapes.

The microbes become the writers or composers of this piece, directing decisions about what data we see and hear. Humans are the performers or interpreters. This reversal engages with questions about non-human agency, and creative and communicative potential of our microbial neighbors.

These projects reveal the power of sound as a creative and expressive medium for not only sharing the story and life contained within soil but as an indicator of soil health.

#### TWO PAINTERS' COLLABORATION WITH SOIL - A SEARCH FOR UNDERSTANDING

A. BERSAGLIERI <sup>1</sup>, P. CASPER <sup>2</sup>

<sup>1</sup> California State University, Long Beach, Long Beach, USA

<sup>2</sup> Ecoartspace, Santa Fe, USA

Leonardo da Vinci said The noblest pleasure is the joy of understanding. Scientists and artists are both in the business of trying to understand the world around us by asking a lot of questions. Whether we rely on experimentation, data analysis, visual analysis or personal experience to find answers, we are all continually asking questions. There is a long history of artists and scientists looking to soil as a way to analyze, investigate, understand and interact the earth.

Pamela Casper and I have both been experimenting with burying cloth as a way to use the soil as a creative partner.

For Pamela, the fascination of soil's cooperative relationships among fungi, tree roots, plants, and other organisms are a driving force and represent the theory of cooperative evolution. The paintings are a visual concept of underground life systems difficult to observe and that unfold endlessly. The resulting watercolors integrate nature's mark making represented on urban and rural buried cloths. The actual cloth is integrated into each final work, resulting in a rural and urban invented underground map, which probes how life processes fit together.

Inspired by Albrecht Durer's, Great Piece of Turf from 1503, I dig shovels full of soil from my suburban yard and bring it into my studio to observe. The resulting drawings and paintings are portraits, a type of record keeping, a way to log and organize and communicate the observed. The buried is used as a substrate to draw attention to the evidence of the soil activity vs how the soil itself looks in its static state. The paintings are oil paint (pigment and oil) and the drawing is done with ink and charcoal that I have made from the dirt and wood found on sight.

This talk will present images of our work, discuss its connection to the science of soil and contextualize it within a broader art historical context.

**BURIAL SHROUD: A MULTISPECIES AND ECOFEMINIST PERSPECTIVE ON HUMAN/MICROBIAL RELATIONSHIPS IN SOIL FERTILITY AND DECOMPOSITION, AS EXPRESSED THROUGH ART.**

D. PINDELL

<sup>1</sup> Olympic College, Art Department, Bremerton, USA

<sup>2</sup> Ecoartspace, Santa Fe, USA

Recent forays from the environmental humanities into the subject of soils have explored questions of caring for soil as it cares for us through food production, and speculation into Western views of labor and colonization. The relevance of these philosophical inquiries arises when the time comes to apply the hard-won data of science to the motivation of the general public, expressed through attitudes, actions, and policies regarding the preservation and improvement of soil ecosystems. The ecological imperative is clear - soil feeds the world - yet necessary action lags far behind the need. How might art serve to bridge that gap?

The Soil Dialogs working group, a collective of artists and scientists, began a long-term inquiry with the simple "cloth burial" method of envisioning soil health as the central prompt, then radially expanded with a broad range of sensory, aesthetic, and intellectual expressions. This presentation offers examples with a particular focus on deep empathy and kinship as pathways for connecting humans with the more-than-human, multispecies, microbial reality of soils.

As an example, Burial Shroud is a textile sculpture that uses these buried, stained, and microbially munched textiles to expand our concept of our human selves into a fully reciprocal, embodied and entangled relationship with the microbial life of healthy soils. Burial Shroud asks us to engage with our own decomposition after death. We must give up the identity of ourselves as an envelope separate from the activity and agency of the microorganisms both inside and outside of our bodies.

Why is this radical reframing of relationships necessary? The extent of human empathy toward our multi-species world will outline the extent of our long-term survival on this planet. Burial Shroud recognizes soil microbes as kin, the porosity of boundaries between species, and mortality as an antidote to the human hubris that drives abuse of soils.

#### SKY INSIDE THE SOIL – ARTISTIC RESEARCH OF THE RHIZOSPHERE AT A SUPERFUND SITE IN BITTERFELD-WOLFEN

A. TOLAND <sup>1</sup>, C. EKTANDER <sup>2</sup>

<sup>1</sup> Bauhaus-Universität Weimar, Weimar, GERMANY

<sup>2</sup> Bauhaus-Universität Weimar, Weimar, GERMANY

“The sky. What kind of a feeling was it as I let it settle upon me, absorbing the toxic yellow-gray smog into my consciousness, counting the high funnels from which it spewed out and then hung like a roof over the city?” (Monika Maron, 1981). What traces of yellow-grey smog from Maron’s controversial critique of environmental degradation in the former GDR are visible forty years later? In Bitterfeld-Wolfen, industrial heritage is a fundamental part of the cultural fabric of the city. Literally. Cellulose-choked wastewater from the film industry, combined with a slurry of chemical fibers from Soviet era synthetic textiles production, were once richly discarded in the quarry ponds of the former brown coal mining pit nicknamed “Johannes”, now commonly known as Silbersee (Silver Lake).

“The Sky inside the Soil” is a multi-phase artistic research project that explores the rhizosphere and its inhabitants in an environment of extreme toxicity. Following the seasonal cycle of ruderal plants growing around Silbersee, we re-imagine the historical trajectories of labor, leakage, and repair on the former mining pit once used for wastewater from the former ORWO film factory and chemical textiles plant. In a series of print works, we use historical images, field photography, and pigments derived from plant biomass to reflect on the social, economic, and aesthetic dimensions of pollution through the medium of silkscreen – a tightly woven nylon mesh, not unlike the synthetic nylon products once manufactured in Bitterfeld-Wolfen. We consider changes in viscosity over time and invite an embodied understanding of such changes through the repetitive process of silkscreen printing: prepare, pour, flood, stroke, lift, repeat. In this iteration of the project, we buried screen-printed cotton handkerchiefs bearing historical images of polluted skies along the lake’s embankment. While atmospheric pollution is no longer visible, traces in the topsoil are revealed through soil quality testing and analysis. What once hung like a roof over the city now belongs to the rhizosphere.

##### UNDER THE CONCRETE: EXPLORATIONS OF SOIL BIODIVERSITY THROUGH ART AND SCIENCE IN THE LOS ANGELES RIVER

L BON , M GARCIA

Metabolic Studio, Los Angeles, USA

As Los Angeles has grown, and so has the need for water to sustain it. Bending the River is an adaptive reuse of LA River infrastructure and will divert a portion of the LA River, treat the water using a native wetland habitat, and then distribute it to the 52-acre adjacent LA State Historic Park.

In-river construction for Bending the River included excavating a trench 90m long, to install clay pipes to carry the water to Metabolic Studio, and a 20m deep well, to receive the diverted LA River water before it passes through to the wetland treatment. According to traditional construction practices, that 4000 cubic meters of excavated soil should be sent to the landfill. Instead, we preserved this valuable soil for further study.

During the well excavation, we took soil samples every 1.5 meters - two 64L boxes and two 50mL tubes were immediately placed in the freezer, and two 3L jars in the refrigerator. The remaining soil was stored at room temperature in an empty warehouse. Because of the site's industrial past, every 1.5m in situ, we tested the soil for heavy metals using a handheld XRF analyzer. Fortunately, both lead and arsenic readings were at safe levels.

One area of interest was biodiversity. We performed a preliminary carbon dating analysis at five different depths, and the results indicate carbon present from 6,000 to 9,000 BP, the era of the Early Chumash people. We also conducted germination experiments and observed plant, moss, and fungi species that could correspond to seeds preserved under the LA River's concrete. Additionally, we used paleogenomic tools, and extracted environmental DNA to identify the genetic legacy of the organisms that lived in these ecosystems.

Because of the size of our soil sample, we plan to continue our experiments, looking at the past of this soil, but also towards the future, as we discover new stories to tell about the ground beneath our feet.

##### THE EXPANDED SOIL PROFILE, A TOOL FOR TRANSDISCIPLINARY SOILS RESEARCH: REFLECTING ON SUCCESSES, OBSTACLES AND NEXT STEPS AFTER FIVE YEARS OF COLLABORATION

K. LAWLESS<sup>1</sup>, E. GREGORICH<sup>2</sup>, H.H. JANZEN<sup>3</sup>

<sup>1</sup> Huron University, London, CANADA

<sup>2</sup> Agriculture and Agri-Food Canada, Ottawa, CANADA

<sup>3</sup> Agriculture and Agri-Food Canada, Lethbridge, CANADA

Problems threatening the biosphere—climate change, food insecurity, biodiversity loss, contamination—cannot be resolved without restoring soils, the complex living systems undergirding all lands. Solving these ‘wicked’ problems by renewing soil will demand a transdisciplinary approach. Our transdisciplinary method, the Expanded Soil Profile (ESP), seeks to map the complex web of relations (i.e., cultural, historical, and physiographic) that embody a specific soil. Expanding on the conventional profile by extending it vertically, temporality, and conceptually, the ESP blends instruments of soil science (i.e., biochemical analysis), social science (i.e., political economic analysis) and humanities (i.e., semiotic analysis) to assess soil care practices and propose future pathways for soil and land use, management, and stewardship. Ultimately, it amplifies traditional soil sampling and analysis with qualitative research to decipher a cohesive, integrated narrative of how humans have lived with soil, and how realigned social and cultural relationships with soil might begin to resolve unfolding threats to the biosphere.

In this paper, I’ll discuss our transdisciplinary collaborations at two organic farms in Canada, and I’ll reflect on the difficulties of working across disciplines and sectors. First, I’ll explain our methodology, which involved: (1) collecting soil monoliths and samples from three main genetic horizons in a virgin forest and adjacent cultivated field and analyzing them to compare physical, chemical, and biological properties and (2) interviewing key informants and conducting historical research to show the dynamic field of symbolic interaction overlaying and interweaving with the soil, from management practices and worldviews to social-ecological systems and agricultural policy. Next, I’ll share our findings, which show that soil care practices guided by an ecological mindset correlated in both cases with increased soil health, indicated by high levels of soil organic carbon. Finally, I’ll discuss some of the difficulties in working across disciplines and sectors, including the absence of a common language, and some of the successes we experienced, particularly the use of the soil monolith as a tool for dialogue.

##### THE NANTESBUCH SOIL INITIATIVE – FOSTERING SOIL KNOWLEDGE AND STEWARDSHIP ACROSS SOCIETY

K. SCHNEIDER<sup>1</sup>, R. ..L. NÁNÁSI<sup>1</sup>, U. SCHNEIDER<sup>2</sup>, R. HÜTTL<sup>2</sup>

<sup>1</sup> Stiftung Kunst und Natur gGmbH - Soil, Landuse & climate, Bad Heilbrunn, GERMANY

<sup>2</sup> Eco-Environment Innovation GmbH, Berlin, GERMANY

Soils are the critical zone on and from which humanity lives. Climate change, biodiversity losses and global population growth with ever increasing demand on natural resources illustrate the essential role of soils for the survival of mankind.

Advances in soil science led to productive soil management practices with emphasis on the protection of soil functions. In case of mal-management well established options for restoring soil functions in inter- and transdisciplinary contexts are available.

Despite the available knowledge soils are degrading due to anthropogenic and natural impacts - often enhanced by the effects of climate change. An important reason for this development is the missing societal consciousness for the relevance of soils for human life.

Against this background the non-profit Nantesbuch Art and Nature Foundation ([www.kunst-und-natur.de](http://www.kunst-und-natur.de)) aims at increasing the visibility for the importance of healthy and multifunctional soils. The foundation offers spaces and interdisciplinary programmes for engaging with art and culture as well as nature and landscapes.

Currently the foundation is building a soil competence network. This transdisciplinary structured network gathers soil relevant knowledge and experience from all relevant disciplines and sectors directly or indirectly linked to this topic.

Furthermore, the soil initiative will contribute to a better awareness for soils by utilizing the various pathways of art and culture for an evidence based emotional approach.

The network will gradually be developed towards an international forum in order to address the global dimension of soil-related challenges by enabling an unbiased and open-ended exchange of decision-makers from science, business, politics and the general public. This broad and international engagement requires es a long-term commitment, and the initiative's success will highly depend on the participation of already existing networks and organizations such as the IUSS.

The contribution will detail the conceptual strategy of this unique initiative based on scientific and practical knowledge, highlight some of the recent key activities and indicate opportunities of how to become part of this comprehensive soil initiative.

##### THE SOIL COOPERATIVE RESEARCH CENTRE - BRINGING FARMERS, INDUSTRY AND RESEARCHERS TOGETHER

M. CRAWFORD

Cooperative Research Centre for High Performance Soils, Callaghan, AUSTRALIA

The Cooperative Research Centre for High Performance Soils (the Soil CRC) is a virtual research centre that brings together research, industry and farmers from 39 participant organisations including universities, government agencies, industry bodies and farmer groups from across Australia. It commenced in 2017 with 10 years of funding from the Australian Government and its partners. The main purpose of the Soil CRC is to undertake soil-related research that helps farmers better manage their soil and in turn, improves their productivity and profitability.

Importantly, while the Soil CRC has a focus on soil, it is not just a research centre for soil scientists. A key part of the Soil CRC's success to date has been the involvement of a broad range of social, economic and scientific disciplines working side-by-side with practitioners and end-users (farmers). Farmers, as represented through place-based and issue-based farmer groups, have played a key role in helping to identify priorities, develop proposals, implement projects, interpret results and communicate findings.

In turn, the involvement of 39 participants, including eight universities, has enabled access to a broad range of complementary and diverse expertise and discipline input.

This has not been without its challenges, as individuals and disciplines struggle to communicate in a discourse that is common and understandable to all. However, individual and organisational participants have welcomed the opportunities and synergistic outcomes that have been achieved through this process.

In my presentation, reference will be made to specific examples to illustrate both the learnings and the successes and the values that are implicit in the research activity of the Soil CRC.

#### SOIL INCANTATIONS – A CONVERSATION BETWEEN A SOIL SCIENTIST AND A POET

K VANCAMPENHOUT, L VANCAMPENHOUT

KU Leuven, Leuven, BELGIUM

In this contribution, soil scientist Karen Vancampenhout and professional writer and poet Luc Vancampenhout embark on an extraordinary journey to invite non-specialists to be amazed by the concealed beauty beneath our feet. Inspired by the works of Francis D. Hole and Robert Macfarlane, they leverage the evocative power of poems and incantations to illuminate the essence and narratives intrinsic to diverse soil types. Their work is an interplay between the beauty of soil profiles and the meticulous adaptation of both language and style to mirror the distinct properties of each soil - from the complex and layered stories of palaeosols, over the lingering effects of ancient climate cycles, to the macabre movements of organic matter in Podzols.

In an era where the urgent need to advocate for soil protection and care is undeniable, the duo employs their interdisciplinary approach to bridge the gap between scientific knowledge and artistic expression. By weaving images and words that resonate with the unique characteristics of different soils, they invite participants to explore a world often overlooked but profoundly connected to our existence. And, in turn, foster a deeper appreciation and collective commitment to safeguarding this invaluable resource.

**ASSESSING AND MAPPING SOIL ECOSYSTEM SERVICES IN URBAN AND PERI-URBAN AREA: PROVIDING SUPPORT TOOLS FOR URBAN PLANNING IN THE MUNICIPALITY OF FORLÌ (NE ITALY).**

F. UNGARO<sup>1</sup>, C. CALZOLARI<sup>1</sup>, S. BAZZOCCHI<sup>2</sup>, P. TAROCCO<sup>3</sup>

<sup>1</sup> Consiglio Nazionale della Ricerche, Istituto per la BioEconomia, Sesto F.no (FI), ITALY

<sup>2</sup> Comune di Forlì, Servizio Ambiente e Urbanistica, Forlì, ITALY

<sup>3</sup> Regione Emilia Romagna, Area Geologia Suoli e Sismica, Bologna, ITALY

Urban developers and planners rarely pay attention to the quality of urban soils, to their functions and to the supply of ecosystem services to the citizens. This work contributes to raising awareness about the role of soil in the built-up environment, to provide tools to assess and map urban soils ecosystem services and to highlight the possibility of integrating soil knowledge into urban planning.

In 2023, the urban soils of Forlì (NE Italy), were surveyed, sampled, analyzed, and mapped over an area of ca. 5700 ha. The outcomes of the survey allowed the integration of the existing knowledge about soils and land use with the urban plan and provided the basis to produce a 1:10,000 map of urban soils. Soil data were interpolated over the entire case study area providing the inputs for locally calibrated pedotransfer functions whose outputs were used to assess a set of seven indicators of soil ecosystem services (SES) potential supply: soil biodiversity, buffer capacity, carbon storage, agricultural production, biomass production, water regulation, and water storage. Results show that for several services, hotspots occur not only in the peri urban agricultural areas but also in unsealed soils within the urban fabric, and that different soils provide high quality services in diverse constellation depending on soil characteristics and degree of sealing.

We estimated that the unsealed soils of the green areas within the city (412 ha) store within the first 30 cm of depth 17,0409 Mg of organic carbon (63,890 Mg CO<sub>2</sub> eq.) corresponding to an average carbon density of 42.2 Mg ha<sup>-1</sup>, which is significantly higher than the corresponding average of the agricultural soils of the municipality (36.8 Mg ha<sup>-1</sup>). Furthermore, over the same reference depth (0-30 cm), the soils of the green areas store up to 17,707 m<sup>3</sup> of water, corresponding to 43 m<sup>3</sup> ha<sup>-1</sup>.

#### MAPPING SOIL QUALITY FROM A URBAN PLANNING PERSPECTIVE: A SUPRA-LOCAL FRAMEWORK REVIEW

M. GIULIANI, M. PEZZAGNO, A. RICHIEDEI

University of Brescia - DICATAM, Brescia, ITALY

The problem of soil consumption is well known and developed in international literature, but there is not a univocal definition of soil and soil quality, despite during the decades these concepts have evolved in the scientific community. Without definition is not possible to measure and evaluate the value of soil consumption at the planning scale: so, its effect at wide area is underestimated by local authorities, which should build greater awareness of soil role and enforce soil monitoring. Therefore, this research proposes a soil quality detection framework adequate for the supralocal planning, identifying a consistent list of indicators for better valorising soil peculiarities, services and vulnerabilities, consciously protecting it from degradation and consumption.

On the one hand the coordination and strategic role of supralocal planning should support organic and integrated wide-area planning and act as an autonomous and authoritative guide, bringing out supra-municipal issues with respect to local interests. On the other hand, the research outcome could represent a valuable reference for local soil quality characterization and be used as a support for planning decisions for the municipalities, which acquire in this way an effective reference for building more accurate Land Use Maps at the local scale. The municipality coordination about this issue is done by Provinces (NUT3) and regulations and laws are done by Regions. Both suffer a weak condition: Province is a second level administrative body and not all the Regions adopt laws on urban containment. So, a revision process of the planning instruments is advisable, with the ultimate aim to reduce soil consumption.

The indicators proposed at the planning scale could be better understood in a provincial-level cartography deepening and detailing the soil quality characterization, useful then at municipality level. Soil quality is detected in the widest perspective: the indicators proposed value not only the soil characteristics in physical, chemical, hydraulic terms, but also the services it gives and the main threats it is subjected to.

#### DRAWING RELATIONS: DEVELOPING TOOLS FOR THE PARAMETRIC DESIGN OF SOIL IN LANDSCAPE ARCHITECTURE

L. HARRIS, T. GALI-IZARD

ETH Zurich, Zurich, SWITZERLAND

While soil is foundational to the field of landscape architecture, it is typically addressed as a narrow technical concern late in the design process, once many major decisions have already been made. Designers lack the tools to creatively and iteratively integrate soil dynamics into the early design phases, which limits the potential for the specific soil conditions of a site to influence the landscape design. Not only does this constrain the aesthetic and performative potentials of landscape architecture, it results in urban spaces that are ill equipped to support vibrant nonhuman ecologies. This is most obvious in the well-documented plight of urban trees, which often struggle due to an insufficient volume of appropriate soil.

Recognizing this issue, we have developed a series of parametric drawing tools that support the inclusion of soil dynamics in early landscape design phases. Drawing is a core part of the design process because it simplifies the complexity of the site into a legible abstraction, allowing designers to work quickly yet precisely. The drawing tools we have developed reduce the complexity of soil to several key parameters, such as texture, depth, compaction, and organic matter content. These parameters are integrated into an algorithmic model in Rhinoceros 3D, a common Computer Aided Drafting (CAD) software used by designers. The algorithmic model brings the soil parameters into relation with climatic variables, such as precipitation and potential evapotranspiration. The model enables designers to quickly modify the multi-variable relationships between soil, climate, and vegetation. Since the parametric model is integrated into existing CAD software, these experiments can directly inform design decisions about form, scale, and materiality. In this presentation, we will introduce the drawing tools and methodology through a series of design studies developed by Masters of Landscape Architecture students at the ETH Zurich. The students explored how to transform the surface and substrate of a street in Zurich to meet the needs of urban trees.

#### SOIL RECOVERY, RE-USE AND CREATION IN URBAN MASTERPLANNING – WHAT IS NEEDED TO ACHIEVE POSITIVE OUTCOMES FOR BIODIVERSITY, THE ENVIRONMENT AND SOCIETY

B. LASCELLES

Arcadis, Bristol, UNITED KINGDOM

Soils provide a wide range of ecosystem services important for our environment, society and economy. This has resulted in the overuse and exploitation of soils from many users, often exceeding the natural system boundaries, in part due to the existence of stringent waste regulation compared to non-existent legislation focused on the services which come from healthy soils. There is also a strong element of a lack of understanding of soils and soil forming materials and how they can be re-used by matching soil characteristics to the requirements of the proposed land use.

Soil health is a term which is gaining wider usage, although probably remains a poorly or mis-understood term. Any framework for soil resource recovery and re-use to support urban development needs to be based on the understanding of natural soils, soil function, soil health and recognition of the central role soils play in supporting the sustainable delivery of the biodiversity projects. It also needs to be based on an understanding of what comprises soil forming materials which may be available for re-use and how these can be combined to create sustainable and functioning soils.

This study will present details of what processes and expertise are required to ensure full recovery and re-use of soils and soil forming materials within the urban environment. Examples will be presented, through the project lifecycle, of the information, data and expertise required to ensure the appropriate re-use of available soils and the use of soil forming materials to create soil profiles suitable for the intended end use, whether that is for landscaping, parks, allotments or sustainable drainage systems, for example.

With the right expertise it is possible to use a full understanding of the soil / soil forming resources present as a platform to maximise re-use to deliver multi-functional post-construction systems, providing quality and resilient environments within urban areas which support both biodiversity net gain and the local community.

### 2. Soil and humanity 2.07 132746 - Soils for planning sustainable cities

#### RETHINKING CONSTRUCTION AND DEMOLITION SOIL WASTE UNDER A CIRCULAR ECONOMY FRAMEWORK

A. KOURMOULI <sup>1</sup>, G. WINTER <sup>2</sup>, C. STEVENS <sup>1</sup>, J. QUINTON <sup>1</sup>

<sup>1</sup> Lancaster Environment Centre, Lancaster, UNITED KINGDOM

<sup>2</sup> Environment Agency, Sheffield, UNITED KINGDOM

Since the 1950s, UK has been experiencing high urbanization rates and it is predicted that by 2050 another 0.3 million hectares, in England alone, might be required for housing and infrastructure development. Therefore, million tonnes of soil will be permanently displaced in order to facilitate the development plans and potentially lose its multifunctionality with environmental and financial repercussions.

Urban soils are often overlooked but they play a major role in humans' lives, as the loss of soils functions can have disastrous consequences, for example the loss of soil's water infiltration function can cause increase flooding risk. Steps have been taken through existing policies and guidance to minimise the environmental impacts of construction in England, however soil derived from construction activity is often overlooked. In 2021, 55 Mt of soil waste, deriving from construction and demolition, were received to permitted facilities in England with 97.9% characterised as inert and over 50% of that was sent to landfill.

In an attempt to introduce soil removed from construction and demolition sites to a circular economy framework, we investigated the potential of introducing a soil reuse system in England under existing policy landscape. We collaborated with the Environment Agency, which is an executive non-departmental public body responsible for the regulation Environment of England and Wales. Following a review of existing international soil reuse schemes, a plan was developed for prioritising the safeguarding of soils' multifunctionality and ecosystem services delivery. The scheme was developed with the scope to accommodate multiple soil qualities arisings during development; from naturally occurring excavated soil material to treated contaminated soil, as well as the possibility of soil "manufacture" utilising other waste streams, especially green waste. The establishment of a soil reuse scheme in England and Wales would divert soils from landfill, recognising the value of soil as a non-renewable resource and helping achieve the national circular economy and net zero targets.

<sup>3</sup> Hochschule Weihenstephan-Triesdorf (HWST), Triesdorf, GERMANY

<sup>4</sup> James Hutton Institute and Robert Gordon University, Aberdeen, UNITED KINGDOM

Cemeteries are part of the urban landscape that once established, will remain untouched nearly “forever”, as the presence of human remains prevents alterations. The incomplete decomposition of human remains in cemeteries has long been an unspoken issue in Norway. The contest for land areas, especially in/near urban areas, is greater than ever, inciting the need to find the key factors influencing decomposition in cemeteries. In many cases, the conditions set by law for reuse are not met, and the resulting need to construct new cemeteries adds to the pressure on urban planners. Modern graves and their respective soils have been studied in the last few years to help design suitable soils for new coffin graves. The presentation will report on the findings of a survey of reused graves in six municipalities of Norway, and the subsequent opening of 73 graves where the soil was characterized, and the rate of decomposition was graded based on a visual inspection of the remains. We will also report the first biological elements off a lysimeter experiment that was established to study the decomposition potential of numerous artificial soil mixes.

**Keywords:** Economic, environmental impact, Soil-decomposition interaction, Traditional coffin graves, Artificial soil mixes, Soil properties

#### EVALUATION SYSTEM FOR SOILS IN URBAN PLANNING

B. BIRLI <sup>1</sup>, W. FRIESL-HANL <sup>1</sup>, L. GREINER <sup>2</sup>, M. HERTZOG <sup>2</sup>, S. HUBER <sup>1</sup>, A. KELLER <sup>2</sup>, M. LAUSTELA <sup>3</sup>, R. MILLER <sup>4</sup>, M. TULIPAN <sup>1</sup>

<sup>1</sup> Umweltbundesamt, Vienna, AUSTRIA

<sup>2</sup> Kompetenzzentrum Boden, Zollikofen, SWITZERLAND

<sup>3</sup> Basler & Hofmann AG, Esslingen, SWITZERLAND

<sup>4</sup> Ingenieurbüro Schnittstelle Boden, Lenggries, GERMANY

As soils provide a large range of ecosystem services in urban areas, it should be of high priority to protect them in the urban environment. Soil protection faces the challenge of urban sprawl and land take by roads and infrastructure. Thus, soil protection aims at avoiding or minimizing, or, where this is not possible, mitigating or compensating land take and soil sealing. For urban planning it is crucial to consider the soil quality in current and future development. Therefore, a sustainable soil management approach should be developed using multidisciplinary methods.

In the project 'URBAN soil management strategy' implemented through the CENTRAL EUROPE Programme co-financed by the European Regional Development Funds, helpful strategies for urban soil management have been identified. Some of them will be showcased in the presentation. One of these strategies focuses on introducing compensation measures and validation of soil functions: A handbook was developed for measures enhancing soil function performance and compensating soil loss during the urbanization process. It introduces compensation measures with the potential to restore or improve soil functions in a sustainable and measurable way.

In the recent project DACHBODEN, financed in the framework of the D-A-CH cooperation transport infrastructure 2021, the main goal was the development of a decision tool, which allows an assessment of soil destruction caused by road construction as well as an estimation of the costs incurred for the compensation of the soil destruction. This tool can also be used for an evaluation of impacts and compensation needs due to new buildings or new infrastructure foreseen in urban planning.

This evaluation tool, which combines status of soil functions, evaluation of the intensity of the modification of the soil by road construction and monetary evaluation of the required compensation may provide a basis for inclusion of soil compensation in legal requirements or regulations for urban planning. The functioning of this tool will be explained by means of a concrete example of road construction.

#### SCIENCE-BASED CHOICE OF SOIL MAY IMPROVE THE SUSTAINABILITY OF BLUE-GREEN AREAS IN URBAN SETTINGS

S. ARNESTAD<sup>1</sup>, I. ØKLAND<sup>2</sup>, M. WEINMANN<sup>3</sup>, A. NEMES<sup>1</sup>

<sup>1</sup> Norwegian University of Life Sciences (NMBU), Ås, NORWAY

<sup>2</sup> Norwegian Institute of Bioeconomy Research (NIBIO), Ås, NORWAY

<sup>3</sup> Hochschule Weihenstephan-Triesdorf, Triesdorf, GERMANY

Knowledge about functional soil properties, such as soil physical and hydraulic properties, is crucial for the responsible planning of immovable elements in (peri-)urban landscapes like cemeteries. Soil in Norwegian cemeteries has received more and more attention in recent years due to problems with incomplete decomposition of human remains. These problems prevent property managers from reusing older graves, and lead to the necessary expansion areas allotted as cemeteries which increases the pressure on urban planners. An accompanying presentation by Økland et al. introduced the core problem and the sequence of ongoing actions in Norway to address these challenges. Given the dynamics of grave-turnover, allocation of new cemetery areas is inevitable in many Norwegian municipalities. Such areas are fitted with constructed soils, and under the auspices of circular resource use, there have been several recommendations to use soil mixes that include various coarse materials of natural origin. For example, artificial crushed sand is a cheaper and more sustainable option to natural sand, which is already being used in new cemeteries and urban greening facilities. However, limited knowledge exists about the properties of these artificial soil components and the resulting soil mixes, and they are suggested to have different porosities and different hydraulic behavior than their natural counterparts of the same size fraction. A lysimeter experiment was established with different soil types, including crushed sands, natural sands and their mixes, to study their decomposition potential. We have performed saturated and near-saturated infiltration tests in situ on 8 such soil mixes, and subsequently sampled them for laboratory analysis of basic physical and chemical properties, soil water retention, as well as 3-D X-ray tomography imaging. This presentation will report on and compare these characteristics and put them in context with initial indications of decomposition potential presented by Økland et al. in the same session.

### 2. Soil and humanity 2.07 132746 - Soils for planning sustainable cities

#### FROM LAND USE TO LAND RE-USE: INTEGRATING CIRCULARITY IN SPATIAL PLANNING

E. FERRAIOLI, G. LUCERTINI

Iuav University of Venice, Department of Architecture and Arts, Venice, ITALY

In the current global context, the destructive effects on the territory due to the progressive reduction of soil fertility and the increasing scarcity of natural resources are highlighting that the linear model of expansion, on which the growth of urban areas has historically been based, is no longer sustainable. This model is evidencing today, more than ever, that the presence or absence of spatial resources can have a strong influence on the structure of urban landscapes in contemporary cities.

These landscapes are closely linked to the types of available soils, whether they are virgin and fertile, polluted or associated with unused, underutilized or inaccessible buildings. It is precisely the soil resource that intervenes in environmental sustainability policies, and in particular in those developed within territorial planning processes, as the main physical support for human transformations and as a significant component for the ecosystemic adaptation of urban environments.

In this perspective, it is therefore necessary to rethink current models to structurally reduce soil consumption and limit the loss of associated ecosystem services, through processes of reconstruction, rebirth, prevention, care and reuse of the territory, and the dissemination of a new territorial paradigm that looks towards circularity.

The focus is particularly on the possibility and potential to act in discarded, abandoned, unplanned or neglected peri-urban contexts, deprived of their function, generally recognized as waste landscapes, to be recognized as reserves of territory to be reused and as enabling contexts for the activation of more circular and structured territorial regeneration processes.

The adaptive reuse of these contexts aims, therefore, to integrate into a circular economic system, focused on maximizing the reuse of resources, an approach that considers the soil as a valuable and limited resource, to be preserved and enhanced, proposing the development of the idea of a circular use of land, capable of redefining territorial planning models, leading to a more sustainable management of urban resources and to more resilient cities.

**Keywords:** soil management, circular spatial planning, adaptive reuse, waste landscape transformation, territorial regeneration

#### MULTI-LAYER CONSTRUCTED TECHNOSOL SYSTEMS WITH DIFFERENT CONFIGURATIONS FOR GREEN ROOFS: RHIZOBOX STUDY

M. SNEHOTA<sup>1</sup>, R. WAHAB<sup>1</sup>, M. PETREJE<sup>1,2</sup>, P. HECKOVA<sup>1,2</sup>, B. RYBOVA<sup>1,2</sup>

<sup>1</sup> Czech Technical University in Prague - Faculty of Civil Engineering,, Prague, CZECH REPUBLIC

<sup>2</sup> Czech Technical University in Prague - University Centre for Energy Efficient Buildings, Bustehrad, CZECH REPUBLIC

This study evaluates the performance of multi-layered soil systems for green roof applications, which are common in blue green infrastructure. Unlike single-layered soils, these systems have different evapotranspiration, infiltration, contaminant removal, and plant support properties. However, the water and solute transport across the layer interfaces is poorly understood. We built 18 rhizoboxes with one, two, and four-layered soil systems on a raised bed on an open-air roof. We used intensive green roof substrate and coarsely grained expanded clay as the layer materials. We report the initial results of the first nine months of monitoring, during which we planted two plant species in the rhizoboxes after starting with bare-soil. We measured the water balance components to assess the hydraulic functioning of the soils. We also applied invasive and noninvasive methods to investigate the capillary barrier, finger flow, and air entrapment phenomena in the multi-layered soils. We adapted a modeling approach for water and solute transport in natural soils to multi-layered constructed soils. Our study aims in long term to provide valuable insights for the design and management of green roofs with multi-layered soils.

#### SOIL INFORMATION EXTRACTION FOR URBAN PLANNING THROUGH REMOTE SENSING

D. POLI, G. CEOLA, T. MAFFEI

AVT AIRBORNE SENSING ITALIA SRL, Trento, ITALY

Remote sensing is commonly used for thematic information extraction of the land cover from hyperspectral and thermal images. Among the available remote sensing platforms, satellites are the best known. However, although their good spectral coverage (i.e. VNIR, SWIR, LWIR), their spatial resolution is poorly effective for urban planning. At the urban level, aerial surveys guarantee very high spectral and spatial resolutions. Using hyperspectral aerial images detailed classification maps of the surface materials can be obtained, showing different soil coverages (bare soil, sand, asphalt, gravel, concrete...), roof materials, asbestos, solar panels, and similar. This classification is also critical for land surface temperature retrieval in combination with thermal images and for the calculation of urban ecological indices such as runoff coefficient (in Figure), infiltration and imperviousness. It is also possible to classify tree species and to study the health of vegetation (e.g. nitrogen content, water content, etc.) or soil properties using spectral indices (i.e. montmorillonite content). Aerial thermal imagery acquired in winter time is useful for identifying underground heat losses, detecting poorly insulated buildings and studying any relationship between soil and heat. Aerial thermal flights in summer time are fundamental to study the generation of heat islands or the mitigation effect of water. On rural soils they can show the distribution of water or fertilizers. The presentation will show and critically discuss the results obtained in AVT Airborne Sensing from hyperspectral and thermal aerial surveys on the cities of Ferrara (Italy) and Graz (Austria), using the AisaFENIX hyperspectral sensor and the DualDigiTHERM thermal camera. In Ferrara the thermal flights were executed in January and July 2023 (day and night) and the hyperspectral one in July 2022. In Graz the thermal flights were performed in September 2021 and one hyperspectral flight in October 2021. Part of the activities is co-financed by the Horizon Europe USAGE project (no 10105995).

#### A METHOD FOR ASSESSING SOIL ECOSYSTEM SERVICES TO IMPROVE LAND USE PLANNING DECISIONS AND PRESERVE HIGH QUALITY SOILS

##### B. VRSCAJ

Agricultural Institute of Slovenia, Ljubljana, SLOVENIA  
Faculty of Environmental Science, Velenje, SLOVENIA

Soil sealing is one of the greatest threats to soils in Europe. The soil ecosystem services (SES) are numerous and not easy for the layman to recognise and understand. Spatial planners usually do not know much about soils, different soil qualities and, above all, the ecosystem services that soils provide. When planning cities or infrastructures, better or worse planning decisions can be. Planners have to choose between different planning options and can avoid sealing the best soils. In order to follow the principles of rational soil, an effective method and an automated tool that helps to recognise which soils are the best would be useful.

This paper presents a method for assessing the SES in urban planning. The method addresses the eleven key ecosystem services that are important for four key human and environmental needs: healthy food, drinking water, safe environment and climate change mitigation. Method consists of two steps. In the first step, the ability of the soils in the planning area to provide the most important SES is assessed. Empirical algorithms were developed and embedded in the Excel tool, which analyses a selection of very basic soil parameters: Total soil depth, topsoil organic matter content, acidity, and nutrient content. The ability of the soil to provide SES is scored from 1 (worst) to 100 (best). The optional fifth criterion is soil pollution. In this case, the tool analyses the concentrations of heavy metals in topsoil, persistent organic compounds, HCH&PAH using national soil pollution limits. In the second step, the tool evaluates each planning option in terms of land sealing and soil quality. Comparing the scores of the planning options in terms of soil ecosystem services within the same planning area enables the selection of the better planning decision and therefore the preservation of the best soils.

The method can help to limit land take and soil sealing, as set out in the EU Soil Strategy for 2030.

Educating children and young people is a duty of science to promote the sustainability of the soil resource as a common good to be preserved. Constructing the knowledge of this audience focused on soil conservation offers society opportunities to learn how to care for our natural resources through a respectful balance with nature, fostering a culture of protection for our most precious asset, the origin of life. Within these principles, we understand that education plays a fundamental role in achieving a balanced planet for the living beings that inhabit it. In a playful and enjoyable manner, this special audience is invited to understand that within the soil live very small animals that play a vital role in ensuring we have clean water and food because they help us take care of this resource. Furthermore, we are responsible for caring for the soil along with these animals, as co-responsible for maintaining the different scales of life. In this way, we present an award-winning work that secured third place among the 97 competitors from 75 countries in the first edition of the competition promoted by the International Union of Soil Science (IUSS) and the Food and Agriculture Organization of the United Nations (FAO/GSP), under the theme 'keep the soil alive, protect soil biodiversity.' The book provides a simple approach to the importance of the beings that are part of the biodiversity of the House of Life (the soil) for our larger home, planet Earth. Originally written and published by FAO in English, it has already been translated and published in Portuguese and Spanish, with the German version currently being finalized. It has reached over 276 institutions in more than 73 municipalities across over 21 states in Brazil, 15 countries, spanning 4 continents. These institutions have undertaken various educational activities with the book published by Embrapa, contributing to the popularization of soil science.

##### SOIL EDUCATION – CURRENT STATE AND CHALLENGES FOR TEACHING 'DIGITAL NATIVES' GENERATION

P. CHARZYNSKI<sup>1</sup>, M. SWITONIAK<sup>1</sup>, M. URBANSKA<sup>2</sup>

<sup>1</sup> Nicolaus Copernicus University in Torun, TORUN, POLAND

<sup>2</sup> 10th Secondary School named after prof. Stefan Banach, TORUN, POLAND

One of the challenges of the modern world is to increase social awareness of the environment and geography lessons create an opportunity for transferring the skills of conscious management of the Earth's resources. The research clearly shows that soils topics are underrepresented (Charzynski et al., 2022) and students lack an awareness of threats related to the environment (Urbanska et al., 2022). The awareness of threats related to various Earth spheres is considerably differentiated. Research shows that the soil issues are the least known in this aspect. Soil education is deficient in many countries. In schools, soil topics are usually taught briefly and with little detail. This may result in students' perceiving the pedosphere as less important than the other spheres– “just” ‘dirt’ we walk on! A proper approach to the issues of sustainable development without an full knowledge of the environmental threats is impossible.

How to encourage a “digital native” to understand the soil - something so “down-to-earth”? The best option is to change the way of knowledge transferring to make this process much more attractive for modern generations. There are a lot of possibilities: mobile games related to soil (free game-based learning platforms) or on-line and off-line mobile applications for the soil profile description to combine soil education with ecological issues and edutainment social networking service. This motivational, challenging, and rewarding digital environment helps learners work toward a goal while choosing actions, and experience the competition and consequences of those actions (experience level/ranks/digital rewards/skills badges/points). This kind of interactive competitive game-based techniques in learning process can be a perfect way to increase public awareness of soils. “ Learning by doing” or even “learning by playing” is a key aspect of multitasking nature of digital natives as well as the ability to apply the knowledge in practice.

<sup>4</sup> Universidad Nacional Autónoma de México, Ciudad de México, MEXICO

In science education, fostering a connection between children and the natural environment is crucial. Soil and paleosol sciences, often overlooked in traditional curricula, play a vital role in shaping our understanding of Earth's history and sustaining life on our planet. Introducing children to these disciplines can profoundly impact their appreciation for the environment and scientific inquiry. Paleosols, or ancient soils, provide a fascinating window into Earth's past. By studying these remnants, children can explore the geological and climatic changes that have shaped our planet over millions of years. This connection to history helps children appreciate the dynamic nature of Earth and the importance of safeguarding its future. The Mystery of Ancient Soils! The children's booklet results from a collaborative effort by the INQUA Paleopedology Working Group, IUSS Paleopedology Commission, and IUSS Young and Early Career Scientists. This project is an educational illustrated short story focused on the concept of soil memory (a fundamental pillar of contemporary paleopedology research), as well as the features of the soil throughout geological history. The story features youthful characters and incorporates elements of cultural significance to vividly underscore the importance of modern and ancient soils as facets of our shared heritage. This book is now available in eleven languages: Spanish, English, French, Polish, German, Russian, Portuguese, Hebrew, Arabic, and Turkish. The Mystery of Ancient Soils! It will not only contribute to educational outreach and help preserve our understanding of soil heritage for generations to come but also promises to be a valuable addition to paleopedology.

<sup>5</sup> BIOAPLIC Group. Department of Functional Biology, Faculty of Biology. University of Santiago de Compostela, SANTIAGO DE COMPOSTELA, SPAIN

<sup>6</sup> INIA, Forest Research Centre, Department of Forest Dynamics and Management, Forest Fire Laboratory, MADRID, SPAIN

<sup>7</sup> Department of Forest Engineering, University of Cordoba, CÓRDOBA, SPAIN

Forest fires are a global complex, especially in Mediterranean ecosystems, seriously impacting the environment, rural development, and the economy. Although there has been substantial research and technical advances in recent years, large areas are burned annually and in most cases restoration or soil conservation practices are not adopted. The Plantando Cara al Fuego (PCF project, FacingFire) is an initiative that proposes the reinforcement of training capacities of young students (from secondary school to university) on wildfire management.

Noteworthy, the project introduces the Service-Learning (S-L) approach, an educational methodology in which students learn while acting to solve real problems. Multidisciplinary teams of students participate in prevention, restoration and awareness-raising projects in areas affected by fires. Regarding soil conservation, students know the processes of soil degradation processes and different techniques for soil protection and restoration. Nevertheless, other important fire aspects are considered as forest fuel management, fire prevention, environmental awareness, and outreach/communication.

Currently, within the framework of the Spanish Ministry of Science and Innovation and the Erasmus+ program, the initiative has expanded and different Spanish regions (<https://www.plantandocaraalfuego.org/>) and some European countries (<https://facingfire.eu/>) are adopting the S-L methodology to transfer knowledge and to improve the training of new generations in forest fire management and soil protection. One of the main outputs was the FOREST FIRE TRAINING NETWORK, hosted at FUEGORED (<http://fuegored.weebly.com/>).

Since the beginning of the project, >100 university students from different disciplines (forest sciences, education, biology, audiovisual sciences, journalism) and >20 agents (primary and secondary schools, local and regional administration, forest communities, companies, NGOs) have participated in >15 projects. In general, participant responses were highly positive, since S-L projects served to create an environment that facilitates learning on different environmental topics including soil conservation and restoration. In addition, other relevant aspects of S-L projects are the interaction of students from different disciplines, the application of theoretical contents, knowledge transfer or the exchange of good teaching practices between participants.

<sup>1</sup> BENEMÉRITA UNIVERSIDAD AUTÓNOMA DE PUEBLA, PUEBLA, MÉXICO

<sup>2</sup> SOCIEDAD MEXICANA DE LA CIENCIA DEL SUELO, CHAPINGO, MÉXICO

Así son los suelos de mi nación is an educational project that began in Mexico in 1986 with the support of Fundación UNAM. Currently, it is a cross-cutting project throughout Latin America. Its purpose is to educate new generations in preserving and conserving soil as a common good. This paper aims to present the activities and educational tools in the teaching-learning process of soil in children and young people in Mexico, carried out within the framework of the Symposium on Educational Innovations in Soil Science Teaching. The Symposium has been held uninterruptedly for the last 17 years; one of its particularities is that children and young people are responsible for presenting presentations on topics and research results related to the soil; within this event, soil scientists of the country are involved in didactic workshops and simple practices that strengthen the understanding of the soil in topics related to soil functions, biodiversity and degradation. The average number of participants in the last three events is 145 students from preschool to high school, 22 researchers and 12 teachers; as a result, continuous work collaborations have been generated among the participants, allowing experts to carry out outreach activities and identify soil as an element of great importance in socio-ecosystems; likewise, the Symposium has awakened interest in conducting simple research from an early age in elementary schools, as well as motivated the development of early vocations. A point to highlight is the recent inclusion of indigenous schools, which allows the identification of their cosmovision about this natural common good and the exchange of knowledge among participants from rural and urban environments. In this context, the Symposium is seen as a didactic-pedagogical tool of great importance in teaching soil science.

#### THE IUSS GOES TO THE SCHOOL

L.B. REYES-SÁNCHEZ

UNAM & IUSS, Cuautitlán Izcalli, MEXICO

Not having a fertile soil that allow us to have enough food and water is already a serious problem, but more serious are the social situations that its deficit engenders: loss of food safety and public health, poverty, displacement, inequality, violence, and injustice as a result of famine (Reyes-Sánchez, 2012 & 2015). The loss and degradation of the soil resource means the loss of all terrestrial flora, and with it that of the fauna that it feeds (Reyes-Sánchez, 2018). It also means a terrible loss of biodiversity at planetary level, a serious destruction of the food chain of which we are a part, as well as the reduction of its capacities of available water reserve and C capture to lessen climate change in the long term but in real terms. In this context the protection of the soil resource and an interdisciplinary and innovative education and practice of sciences to raise citizens' awareness on the importance of its preservation -working all the sciences as a team in a mediatised world-, are keys to achieving the Sustainable Development Goals, and therefore, are the long-term goals and priority objectives of the International Decade of Soils of the IUSS (Horn, 2015), and they base its educational project (IUSS, 2022).

#### SOWING SEEDS OF AWARENESS: THE GSP AND IUSS UNITE FOR YOUTH SOIL ADVOCACY

I. VERBEKE<sup>1</sup>, C. HUMURA<sup>1</sup>, M. FURENTI<sup>1</sup>

<sup>1</sup> FAO - Food and Agriculture Organization of the United Nations, Global Soil Partnership of the Land and Water Division, Rome, ITALY

Established in December 2012, the Global Soil Partnership (GSP) of the Food and Agriculture Organization of the United Nations (FAO) serves as a globally recognized mechanism with the mission of elevating soils in the global agenda and advocating for sustainable soil management. Since its establishment in 2014, World Soil Day (WSD) has witnessed an increasing level of participation and engagement. In 2023 alone, the global community organized over 10 000 events and featured in 569 articles in leading newspapers, reaching nearly 1 billion people. This day is marked by various events, actions, and initiatives aimed at raising awareness about the potentialities and challenges of sustainable soil management.

Since 2021, the GSP, in collaboration with the International Union of Soil Sciences (IUSS), has introduced an annual booklet contest. This contest invites soil scientists and designers to team up and submit creative book proposals for children based on WSD annual theme. The winning book, designed for children aged 6 to 11, is selected by a committee based on criteria such as creativity, originality, content quality, technical and scientific proficiency, and the artistic/visual impact of the book.

Contributions from participants worldwide, including soil scientists, researchers, professors, teachers, students, practitioners and designers from seventy countries, have resulted in the creation of over 200 booklets.

Each year, a curated collection of ten stories is released, offering a well-balanced representation of entries from various regions. These stories, centred on themes such as soil biodiversity, salt-affected soils, and soils for nutrition, engage children in a fun and unique way, introducing them to the fascinating world of soil. The publication of these booklets strategically captures the interest of young children in soil science during their formative years, moulding them into potential future decision-makers.

Through educational projects, global artistic expression, and engagement with youth, the GSP, in collaboration with the IUSS, has effectively initiated conversations that underscore the importance of preserving soil resources and promoting sustainable soil management.

##### SOILS AWARENESS AND KNOWLEDGE AMONG ITALIAN SECONDARY HIGHER SCHOOL STUDENTS

G. MASTROLONARDO<sup>1</sup>, M.T. CECCHERINI<sup>1</sup>, P. CHARZYNSKI<sup>2</sup>

<sup>1</sup> Department of Agriculture, Food, Environment and Forestry, Università degli Studi di Firenze,, Firenze, ITALY

<sup>2</sup> Nicolaus Copernicus University, Torun, POLAND

Soil is one of the most important natural resources and its degradation is one of the global environmental challenges. However, compared to other natural resources and their related threats, soils are often ignored or overlooked by general public. Indeed, there is a lack of soil awareness and knowledge received through formal and informal education. The goal of protecting soil resources cannot ignore soil awareness and education.

In Italy some soil science basic concepts have been added quite recently in primary and secondary lower schools scientific curricula, but the decision of teaching soil related topics is up to the teachers. The latter often have little knowledge about soil and could not feel comfortable to teach about it. Last, apart from agricultural technical schools, soil teaching is lacking in secondary high schools, even in the earth sciences curriculum.

To test the soil awareness and knowledge of high school students, we conducted a survey among several schools in Tuscany, Italy, which took part in an university dissemination programme related to environmental issues. The results show that, although most of the students had been taught at school about soil, they were not aware of the role that soil plays in human life and ecosystem services provision. Students were generally aware of problems related to air and water pollution, but less than a half of them shared the same concern about soil pollution and just a minority was aware of the role of soil in climate change mitigation. Overall, there was a general low awareness of soil; most of the respondents live in cities and do not even associate the urban environment with soil. Young people's lack of soil awareness is a crucial issue soil scientists should debate about as it can hinder the interest and knowledge of soil value for the whole society, as well as decreasing over time the number of future soil science students, eventually worsening the problem.

### 2.09 133548 - Microbiome as a common thread from soil to human health: Interaction, Impact and Role of Soil-Plant-Human Microbiome as a new challenge of innovative agriculture and quality food

#### PLANT MICROBIOMES AND THE PRODUCTION OF NUTRACEUTICAL COMPOUNDS: THE CASE OF MYCORRHIZAL SYMBIANTS

M. GIOVANNETTI

University of Pisa, Pisa, ITALY

Mycorrhizal symbioses are beneficial associations between soil fungi and plant roots, involving about 6,000 fungal species and 240,000 plant species. Among the different mycorrhizal symbionts, arbuscular mycorrhizal fungi (AMF) are the most important, establishing the symbiosis with about 80% of land plants, including the most important food crops, such as rice, corn, barley, wheat, legumes, vegetables, fruit trees. AMF receive carbon from the plant, in exchange for mineral nutrients absorbed from the soil and translocated to the host plant, by means of an extensive network of extraradical hyphae, where P and N transporter genes are differentially expressed. Plants colonized by AMF show enhanced growth and higher tolerance to biotic and abiotic stresses. Beyond plant growth and nutrition, AMF can modulate plant secondary metabolism and the production of health-promoting compounds: actually, a number of mechanistic studies showed a differential expression of genes encoding for the relevant enzymes, upregulated in mycorrhizal plants compared with controls. The production of antioxidant enzymes and phytochemicals has been investigated in mycorrhizal medicinal and aromatic plants, as well as in many fruits and vegetables, such as grapevine, strawberry, artichoke, lettuce, onion, pepper, potato, tomato. For example, higher levels of antioxidant compounds, caffeic and rosmarinic acid, essential oils and anthocyanins were found in mycorrhizal sweet basil. Large increases in total polyphenolic content and antioxidant activity were reported in artichoke flower heads, the edible part of the plant representing a good dietary source of nutraceuticals. Though, different AMF species and isolates showed differential performance, as one out of six AMF symbionts was the most efficient in the promotion of total phenols and chlorogenic acid content in artichoke, while a higher content of anthocyanins was produced in red leaf lettuce plants inoculated with *Rhizoglyphus irregularis*, compared with those colonized by *Funneliformis mosseae*. Here, an overview is provided on the multiple roles played by plant root microbiomes - AMF and associated bacteria - in the production of nutraceutical compounds.

<sup>4</sup> CREA-CENTRE FOR GENOMICS AND BIOINFORMATICS, Fiorenzuola, ITALY

Agricultural practices can impact the complex interactions between soil, plant and microorganisms, modifying soil fertility and crop resilience to various stresses. In the case of grapes, soil microbiome can also affect its wine-making process and the final quality of the wine, as well as the definition of the terroir. In this study, the microbiome of eleven vineyards representative of the various Barbera d'Asti production areas in one of the most important wine-making territories of Piedmont (Italy) was studied using amplicon sequencing of 16S rDNA V4 gene region for bacterial and archaeal and ITS1 and ITS2 gene regions for fungal sequences. Biodiversity indices and variations in taxonomic composition among the vineyards were analysed, identifying the taxa that characterize the vineyards differently. Actinobacteriota and Ascomycota were the two most abundant phyla for bacteria and fungi, respectively. As evidenced by the beta diversity data, different vineyards showed different microbial community composition, while the alpha diversity measured with the Shannon index did not show significant variation between vineyards. Based on the different taxonomic composition of the fungal and bacterial soil communities, vineyards could be distinguished into four groups.

Interestingly, a vineyard (located in Castel Boglione) was specifically characterized for lacking common ASV for bacterial and fungal taxa, and another one (located in Mombaruzzo) contained 10 unique ASV, all belonging to Basidiomycota. Fungal taxa common to all vineyards were 39 ASV. A core microbiome was defined by 21 features related to bacteria and 8 features related to fungi. The analysis of the soil metagenome provides new insight into the complexity of the microbiome in this production area, favouring the definition of specific terroirs useful for the valorization of the Barbera d'Asti wine protected denomination of origin.

**OPTIMISING THE NUTRACEUTICAL PROPERTIES OF SAFFRON CULTURES: APPLICATION OF A BACTERIAL CONSORTIUM TO ENHANCE ACCUMULATION OF BIOACTIVE COMPOUNDS AND SOIL BIODIVERSITY**

B FARDA, R DJEBAILI, E SABBI, L PACE, C ERCOLE, M DEL GALLO, D M SPERA, M PELLEGRINI

University of L'Aquila - Department of Life, Health and Environmental Sciences, L'Aquila, ITALY

Saffron (*Crocus sativus* L.) is an autumn-flowering geophyte known for its stigmas. However, the stigmas, stamens, and petals contain several bioactive compounds that can be used for pharmacological and nutraceutical purposes. Plant-microbe interactions have been shown to influence plant growth and the accumulation of bioactive compounds. Therefore, the use of bacterial inoculants could be a sustainable tool to improve the production of bioactive molecules. The aim of this study was to evaluate the effect of a selected bacterial consortium inoculation on saffron plant growth and bioactive compound accumulation in stigmas and petals. Two-year field and greenhouse experiments were conducted during the 2022 and 2023 growing seasons. The saffron corms were soaked in the bacterial inoculum for one hour and dried overnight. The control group was treated with water using the same procedure. The growth of the plants was monitored in both greenhouse and field experiments. During the flowering stage, leaves were collected for chlorophyll estimation, and stamens and petals were analysed for carotenoids, phenolic content, and antioxidant activity. Moreover, stigmas were processed to analyse the main bioactive compounds of saffron, including picrocrocine, safranal, and crocin, following ISO protocols. Soil samples were analysed for enzymatic activity (1-dehydrogenase activity - DHA) and microbiota structure (16S rRNA gene metabarcoding by NGS). Results showed that bacterial inoculation had a positive impact on saffron plants, resulting in earlier and more abundant flowering, as well as higher accumulation of bioactive compounds compared to the control. Furthermore, the bacterial inoculation had a positive impact on soil fertility by increasing enzymatic activity and microbial diversity compared to the control. The study highlights the role of bacterial inoculants in managing saffron crops. The findings demonstrated that microbial inoculants could enhance the nutraceutical qualities and yields of saffron, as well as improve soil biodiversity.

<sup>2</sup> UASVM Cluj, Cluj-Napoca, ROMANIA

Microbial communities in agricultural soils are very diverse associations shaped by the applied management during cropping cycles. Their reaction to changes and perturbations are fast and complex, by modifying the use of resources through multiple levels of interaction. The current context of soil use relies on multiple approaches toward conservation of this resource and maintaining its fertility and functionality. The study of soil functional microbiomes implies both the analysis of their diversity and their reaction to soil management. A comparison between multiple soil sites is necessary to identify the effect of each technological link based on microbiome reaction. The establishment of a control site is necessary to create the basis of comparison. All the changes observed within a treated (or affected) functional community can be related to this level of the microbiome. This value enables the survey of any normal increases in functional microbiome, which is assessed as an intensification, and the expansion of a specific microbiome above the normal level. On the other hand, all the decreases observed can be treated as a normal narrowing due to treatments or even a severe contraction of a specific microbiome. Based on the full exploration of soil functional microbiomes can be detected the functional alteration of specific microbiomes – at guild or group level – produced by the application of a treatment. The reconstruction of a previous soil condition can be forecasted based on synergetic effect of both biotic and abiotic factors at a functional group or guild level, which makes the entire process more specific. The analysis of soil functional microbiomes can be applied both to detect the changes that can occur in a specific soil environment or to assess its current functionality.

#### 2.09 133548 - Microbiome as a common thread from soil to human health: Interaction, Impact and Role of Soil-Plant-Human Microbiome as a new challenge of innovative agriculture and quality food

**ROLE ON THE PRODUCTIVITY AND NUTRACEUTICAL PROPERTIES OF CORN BY NITROGEN-FIXING AND PHOSPHORUS-SOLUBILIZING COMPONENT OF THE SOIL MICROBIOME**

L. PATRUNO

University of Life Sciences King Michael I of Romania, TIMISOARA, ROMANIA

The soil microbiome, comprising diverse microorganisms such as bacteria, fungi, and protozoa, plays a pivotal role in soil health, plant nutrition, and enhancing the nutraceutical properties of crops. These microorganisms are essential for nutrient cycling, maintaining soil structure, and improving the nutritional and medicinal values of plants, which is increasingly important for sustainable agriculture and health-conscious consumerism.

In this context, nitrogen-fixing bacteria within the soil microbiome, like *Azotobacter chroococcum*, *Azotobacter vinelandii*, and *Bacillus megaterium*, are of particular interest for cereal crops such as maize. These crops cannot utilize atmospheric nitrogen directly, leading to a heavy reliance on chemical fertilizers. However, current environmental initiatives, including the European Green Deal and the Farm to Fork Strategy, advocate for a reduction in the use of chemical fertilizers, highlighting the need for sustainable alternatives.

Our study explores the impact of these nitrogen-fixing bacteria on maize yield. By converting atmospheric nitrogen into a form plants can use, these bacteria offer a potential solution to reduce reliance on chemical fertilizers. The field experiments involved pre-planting inoculation of maize seeds with the bacteria and treatments during the growth phase. The experimental setup included a control (non-treated) and three variants, each treated with one of the bacterial species, replicated three times.

Results showed a significant increase in maize productivity, particularly in plots treated with *Azotobacter vinelandii*. This finding suggests that nitrogen-fixing bacteria can serve as a sustainable alternative to chemical fertilizers, supporting increased food production and conservative agricultural practices. Future research will further investigate how these bacteria improve the quality of cereal crops, enhancing their nutritional value. This study not only underscores the potential of nitrogen-fixing bacteria in sustainable agriculture but also emphasizes the broader role of the soil microbiome in boosting the nutraceutical qualities of crops, contributing to a holistic approach to agricultural sustainability and public health.

##### BIOCHAR AS A PREBIOTIC FOR SOIL MICROBIOTA? AN EXPERIMENT IN SALAD FIELDS.

A. PASSERA, F. TAMBONE, B. SCAGLIA, A. FOLLADOR, N. MIOTTI, S. PAGNONI, P. CASATI

Università degli Studi di Milano - Dipartimento di Scienze Agrarie e Ambientali, Milan, ITALY

Microbiota is crucial for fertility of the soil and, therefore, agriculture. Among several substances and practices that can enhance soil microbiota, biochar is emerging as a very promising solution. Biochar not only offers ecological services (i.e. carbon sequestration) but has been reported as providing benefits to cultivation such as better nutrition and pathogen suppression. Despite this, the mechanism of action of biochar is unclear and several studies report different, sometimes even contradictory, results of biochar application, suggesting that both the nature of the biochar and the investigated culture are important variables.

In this study we monitored the microbiota composition from 2019 to 2020 in fields used for chicory cultivation in Northern Italy, comparing three different conditions: i) plots with organic farming management, ii) plots with integrated farming management, iii) plots with integrated farming management and treated with biochar. Each condition was evaluated at three time points, always at the end of a cultural cycle of chicory.

After DNA extraction from the soil, a portion of the 16S gene was amplified and sequenced on an Illumina platform. This metabarcoding data allowed to determine the following dynamics in the microbiota: the strongest driving force in microbiota structure was sampling time but the different treatments, especially organic versus integrated farming, were distinguishable; the application of biochar gave a first response in which the soil microbiota structure became intermediate between organic and integrated management but, in the following time point, the samples either became indistinguishable from the organic management samples, or reverted to the initial integrated management situation; the overall diversity and quantity of bacteria in the soil was not improved by biochar treatment, but the quality of the microbiota became more similar to that of organic management, without losing any productivity compared to the integrated management.

These results suggest that the use of biochar in salad cultivation may help promote a healthier soil microbiota and thus maintain soil fertility.

##### SOIL MICROBIOME AS A RESOURCE FOR HUMAN HEALTH

C. RICE<sup>1</sup>, R. KONZ<sup>2</sup>

<sup>1</sup> Kansas State University, MANHATTAN, USA

<sup>2</sup> University of Kansas, Kansas City, USA

Soils host a large and diverse community of microbes. The soil microbiome is responsible for a wide array of soil functions, including biomass decomposition, delivery of nutrients to plants, water retention, and the suppression of insect predation and disease on crops, among other soil services. Studies have shown that diet is among the major factors influencing the composition of the human microbiome, notably the gut microbiome, which has been associated with important regulatory roles in the immune system and the metabolism of food and drugs. An active area of research is understanding how the soil microbiome directly affects the human gut microbiome. It is well known that the soil microbiome is a reservoir of antibiotic-resistant genes. Additionally, the microbiome is a rich source of bioactive compounds for treating human diseases. Two-thirds of the antibiotics currently used in human medicine are derived from soil microbes, and numerous pharmaceuticals originate from the soil. Given that only an estimated 1% of the soil microbiota have been cultured outside of their natural communities, the genetic diversity of the soil microbiome is believed to be an untapped resource of molecular compounds for beneficial uses in human health and other applications. Because of its direct and indirect relationships to human health, there is a significant need to manage soil resources to preserve future benefits. In agriculture studies, identifying management actions to reduce soil degradation is considered the highest global threat to the loss of the soil as a beneficial human resource.

The human gut microbiome (GM) is shaped by both genetic and environmental factors, and influences many dimensions of health and disease from infancy through adulthood. Recent research has demonstrated several pathways for environmental exposures to affect health via their influence on GM, including exposures to microbes in soils. Soil microbiota have already been correlated with characteristics of human microbiota; however, little is known about direct linkages between the soil microbiota (SM), GM, and health for children in East Africa, where economic, social, and climate factors are driving rapid changes in lifestyles, livelihoods, and landscapes with implications for SM exposure.

In this study we used SM and GM samples collected from 140 children from rural households in western Kenya to assess contributions of the household SM to the child GM. Microbial source-tracking analyses show that, in more than a quarter of households, the proportion of the GM that is attributed to the household's SM exceeds 0.10, and in some households reaches 0.37. To explore environmental correlates of these SM-GM relationships, we draw on household questionnaire data to identify potential contributions of drinking water sources, hygiene and sanitation, and household economics to these observations. We find that households using surface drinking water sources, including Lake Victoria and surrounding waterways, have significantly higher proportions of the GM attributed to the local SM when compared with other sources (Kruskal-Wallis  $p < 0.01$ ). Using data from iSDAsoil, ISRIC SoilGrids, and CHIRPs, we further explore contributions of soil classes, soil properties, and local climate to the observed SM-GM relationships. Using several machine learning approaches, we find that 1-month prior precipitation and temperature, soil pH, and soil bulk density are among the strongest predictors of the proportion of the GM attributed to the SM. These results show that the SM contributes to the GM for children in rural households, and that these contributions may be moderated by characteristics of the landscape including soils and seasonal climate.

**MEDEUBIOTICS: BUILDING RESILIENCE AGAINST ENVIRONMENTAL POLLUTANTS THROUGH AGROECOLOGY, ORGANIC MEDITERRANEAN DIET AND EUBIOTICS TO PROTECT THE ECOSYSTEM, SOIL AND HUMAN HEALTH.**

L. MONTANO

LOCAL HEALTH AUTHORITY ASL SALERNO, Salerno, ITALY  
UNIVERSITY OF TOR VEGATA, Roma, ITALY

Chemical substances harm ecosystems and cause health issues. Soil erosion, climate change, and monoculture farming contribute to the loss of arable land and reduce crop nutritional value. Agroecological systems prioritizing organic matter input and crop diversification improve soil microbiota and prevent erosion and nutrient leaching. By endorsing environmentally friendly cultivation techniques like agroecology and eubiotic agriculture, which focus on soil microbiota health, higher bioactive compound content can be maintained in food compared to conventional cultivation. This supports the production of food enriched with healing and detoxifying compounds. The Mediterranean organic diet and the eubiotic diet share similarities and emphasize natural and organic foods for health benefits. The EcoFoodFertility research project experiments with more advanced dietary models to build resilience against environmental pollutants, particularly focusing on their impact on reproductive health. From a One-Health and preventive medicine perspective, as intended by Lago Galdston in his definition of Eubiotic Medicine, which goes beyond disease prevention to directly act on the development and overall well-being of individuals in close connection with the environment, the Mediterranean diet with organic foods, combined with eubiotics, seeks to outline a new interpretative horizon in terms of human resilience to environmental pollution. From a biological perspective, pollutants can alter cellular structures through oxidative stress. Imbalances of radical oxygen species (ROS) and antioxidant defenses increase the susceptibility to oxidative stress diseases, making the consumption of a Mediterranean diet with antioxidants crucial. The Mediterranean diet's components like fruits, vegetables, and olive oil possess antioxidants that neutralize ROS and protect cells. Phytochemical compounds in plant foods can prevent or counteract the harmful effects of environmental pollutants through various mechanisms. 'Organic' foods, cultivated based on agroecological criteria, have a higher bioactive compound content than conventional foods. MedEubiotics combines the organic Mediterranean diet with principles from eubiotic medicine to promote preventive medicine and overall well-being in individuals in connection with the environment.

##### THE 'SOIL OF THE YEAR' PROGRAMME IN POLAND

C. KABALA

Wroclaw University of Environmental and Life Sciences, Wroclaw, POLAND

Although people, in particular farmers and foresters, agree that 'soils are important', knowledge of the diversity and functions of soils, as well as an understanding of the need to protect soils, is insufficient in public space. Therefore, the 'Soil of the Year' has been initiated in Poland during the 80th anniversary of the Polish Soil Science Society (PSSS) in 2018, based on the experiences of the German Soil Science Society. The 'Soil of the Year' has a broad formula and emphasizes both scientific aspects and educational and popularizing goals. Rendzina was elected the first 'Soil of the Year 2018', followed by Chernozems, Technogenic soils, Rusty soils (Brunic Arenosols), Alluvial soils, Clay-illuvial soils (Luvisols and related) and Organic soils for 2024. Soil of the year is elected by members of the Commission of the Soil Genesis, Classification and Cartography of the PSSS. Among the scientific activities dedicated to the soil of the year is the symposium (oral and poster presentations) focused on the state-of-the-art and unsolved questions (origin, distribution, classification, degradation, management, etc.) followed by field session. The Special Issue of the Soil Science Annual (IF 1.5) presents a collection of articles (reviews and original contributions). Among educational activities, the following should be highlighted: posters and calendar, in printed and electronic versions, special lectures and presentations for various groups of participants (universities, research institutes, local authorities and offices, public and private companies, secondary and primary schools, etc.), broadcasts on television and radio, advertisements on social media, special events at the soil museum, during 'science festivals' and 'knowledge competitions', etc. The PSSS applies to the permanent patronage and financial support of the Ministry of Agriculture or the Ministry of Environment.

<sup>3</sup> Groupe Eiwa, Péchaudier, FRANCE

<sup>4</sup> RNEST ACTA, Paris, FRANCE

<sup>5</sup> Groupement d'Intérêt Scientifique sur les Sols Info&Sols INRAE, ORLEANS, FRANCE

<sup>6</sup> Réseau Mixte Technologique Sols et Territoires, Schiltigheim, FRANCE

In 2002, the International Union of Soil Science (IUSS) recommended an international day as a global platform for raising awareness on soil issues. In December 2013, the United Nations General Assembly designated December 5, 2014 as the first official World Soil Day.

Every year since 2014, the French Soil Science Society (AFES [www.afes.fr](http://www.afes.fr)) has organized World Soil Day (WSD) on a French scale. The objectives of this event are to :

- Raise awareness of the state of existing scientific knowledge on the theme chosen each year by the Global Soil Partnership (Soil Information Systems in 2024).
- Promote local solutions that can be implemented to preserve soil quality. Since 2017, we organize the WSD in different region every year..

Initially organized as a one-day event, the WSD is growing in scope each year, with 8 days of events in 2023, including more than 20 highlights to reach a wide range of audiences (young people, technicians, scientists, agricultural professionals, the general public, political players, etc.). Nearly 2,000 people, including 500 in person, took part in one of the highlights of the 2023 edition of the JMS, and the special youth event this year reached over 800 young people.

This presentation will explain how the WSD event in France has evolved since its establishment in 2014 to better meet the expectations of various stakeholders in the territories in terms of access to scientifically reliable information on soils. We will also detail the method used to work with French soil networks and host territory players to organize WSD events each year, a key element in the growing success of this event in France. We will also focus on the different event formats organized each year to reach a variety of audiences.

In 2024, AFES also initiated the setting up of a Europe-wide network to exchange experience on the different formats for organizing events around the World Soil Day.

##### ACTION SOIL OF THE YEAR IN GERMANY – LESSONS LEARNED FROM 20 YEARS OF EXPERIENCE

G. MILBERT <sup>1</sup>, D. SAUER <sup>2</sup>, K.H. FEGER <sup>3</sup>

<sup>1</sup> Advisory Board Soil of the Year Germany, Geldern, GERMANY

<sup>2</sup> University Göttingen, Department Physical Geography, Göttingen, GERMANY

<sup>3</sup> tec. University Dresden, Institute of Soil Science and Site Ecology, Dresden, GERMANY

Since 2005, the German Soil Science Society has co-organized the ‘Soil of the Year’ campaign under the joint umbrella of several governmental and non governmental institutions. Under the annually changing patronage of national and federal state ministries, the action has gained great public visibility over the years. Activities are primarily intended to raise public awareness of soils and their functions in landscapes, as well as their crucial role in providing ecosystem services. Thereby, the overall aim of the action is to capture the interest of as many people as possible in order to foster the responsible use and, in this way the protection, of this vital resource. In retrospect, after a period of 20 years, the action has experienced a development from an initially close taxonomic focus to a more ecological valuation of soils and a look at different land use systems and their specific interactions with soils, while the “Soil of the Year” not always necessarily corresponds to one specific soil type anymore. Also, the practice of public relation and communication changed over time. Definitely, the action “Soil of the Year” has become the most successful initiative among various efforts of increasing public soil awareness in Germany.

##### ECHO PROJECT - ENGAGING CITIZENS IN SOIL SCIENCE: THE ROAD TO HEALTHIER SOILS

M. CAGGIANO <sup>1</sup>, T. MIMMO <sup>2</sup>

<sup>1</sup> Re Soil Foundation - ECHO project partner, Turin, ITALY

<sup>2</sup> Free University of Bolzano-Bozen - ECHO project coordinator, Bozen, ITALY

ECHO is a Research and Innovation Action co-funded by the European Union under the Horizon Europe programme, and UK Research and Innovation lasting 4 years – from June 2023 to May 2027. The project aims to engage citizens in protecting and restoring soils by building their skills and enhancing their knowledge on soils. Citizens will actively contribute to the project's data collection, promote soil stewardship, and foster behavioural change across the EU. With 16 partners from Europe and Scotland, under the coordination of the Free University of Bolzano-Bozen, ECHO will develop 28 tailor-made citizen science initiatives across EU Member States and Scotland to collect soil health data from up to 16,500 sites across Europe and Scotland in different climate and biogeographic regions. These unique data will be gathered in a long-term open access repository, the ECHOREPO, with a direct link to the EU Soil Observatory (EUSO) that will enable the citizen science data collected during ECHO to be available for use by scientists, general public, policy makers, farmers, landowners and other end-users, providing added value to existing data and other relevant soil monitoring initiatives. ECHOREPO will provide valuable information about the state of soil health, helping citizens make informed decisions about land use and conservation.

Ultimately, ECHO aims to engage citizens by enhancing their knowledge, stimulating interest in soil health-related issues, and motivating them to protect and restore soils. It seeks to empower citizens by encouraging active participation in data collection and soil science to generate knowledge on soil health for the benefit of all. Additionally, ECHO aims to enable citizens to play an active role and participate directly in decision-making on soil issues based on acquired knowledge.

The project strives to provide local-scale data on soil health to expand and complement established soil databases, supporting critical landscape decisions and policy development. ECHO also endeavours to contribute to the enlargement and enrichment of the EUSO with citizen science data.

##### BRIDGING NARRATIVES ON RESEARCH AND SOIL HEALTH: A TRANSDISCIPLINARY APPROACH CENTERED ON COMMUNICATION AND CITIZEN ENGAGEMENT

V. GRASSO<sup>1</sup>, R. GIUFFREDI<sup>2</sup>, L. CRISCUOLO<sup>3</sup>, L. LAURENZA<sup>4</sup>, C. COLELLA<sup>4</sup>, A. L'ASTORINA<sup>4</sup>

<sup>1</sup> Consiglio Nazionale delle Ricerche - Istituto per la BioEconomia, Firenze, ITALY

<sup>2</sup> Consiglio Nazionale delle Ricerche - Istituto di Ricerca sulla Crescita economica sostenibile, Roma, ITALY

<sup>3</sup> Consiglio Nazionale delle Ricerche - Istituto di Geoscienze e Georisorse, Pisa, ITALY

<sup>4</sup> Consiglio Nazionale delle Ricerche - Istituto per il Rilevamento Elettromagnetico dell'Ambiente, Milano, ITALY

This contribution addresses the intricate dimensions of communication and citizens' engagement as exemplified by the BRIDGES project—an initiative aimed at: Building reflexivity and Response-ability Involving Different narratives of knowledGE and Science. The project explored how transdisciplinarity and extended-peer communities of knowledge production represent a groundbreaking effort in communicating soil health as a complex socio-ecological issue. Through the integration of diverse perspectives from various disciplines, and a regular, inclusive and non-formal internal and external communication activity BRIDGES highlighted the interplay among ecological, social, and cultural factors shaping soil representation. BRIDGES designed and facilitated communication activities engaging researchers from different backgrounds, citizens and local stakeholders through artistic workshops, webinars and a citizen science campaign. Communication was the key to the project to make transdisciplinarity alive and inclusive. It was not framed to disseminate activities, but to build relationships, empower younger researchers and engage people, knowledge and epistemic views at every stage of the process.

With a 40-day citizen science experiment to monitor soils in the urban area of Milan, BRIDGES engaged an extended community of peers to co-produce relevant knowledge. Engaged citizens contributed with diverse perspectives to the intricate fabric of soil health thanks to personal immersive monitoring, meetings, local initiatives and online webinars for a mutual understanding of research perspectives and local concerns. To create new narratives on soil-health the project proposed a collaboration between scientists and artists to stimulate collective imagination. Artistic practices served as a conduit, interweaving scientific concepts with experiences capable of transcending rational thought, thus increasing public awareness of the deeper connection between society and soil health. The data collection on peri-urban soils in Milan emphasized the active role of citizens, involved not as mere data collectors but as knowledge producers. Citizen engagement was framed as an empowering force, encouraging individuals to actively contribute valuable insights to soil health research.

**FOR EUROPE: STIMULATING SOIL LITERACY, SUSTAINABLE SOIL RELATIONS AND USE WITH THE HELP OF CULTURAL SOIL INTELLIGENCE AND WAYS OF ARTS.**

N. PATZEL

<sup>1</sup> DBG German Soil Science Society, commission VIII on Soil in Education and Society, Göttingen, GERMANY

<sup>2</sup> IUSS International Union of Soil Sciences Working Group on Cultural Patterns of Soil Understanding

<sup>3</sup> Büro für Bodenkommunikation, Überlingen, GERMANY

Keep our soils alive and bearing fruits! The outer soils of Europe in responsible accordance with its inner soils? Europe is a multifarious cultural area and has been skilled in powerful war and exploitative use of global natural wealth. At the same time, Europe's long and diverse history also contains many cultural fundamentals and some traditions for sustainable coexistence in nature with its/her/his/our soils.

Let cultural orientational knowledge and new experiences and approaches to direct and indirect soil communication artfully interact. This also with the help of civil society and EU-funded projects. Let our societal and mental landscapes of human-soil relations develop across scales to reach a European cultural soil sustainability.

This presentation is based on work of the IUSS Division 4 Commission 'Cultural Patterns of Soil Understanding' since 2016; and it includes an outlook on the new EU project SOILSCAPE (Horizon 'A Soil Deal For Europe').

##### FIRST TWO YEARS OF THE WORMEX II EXPERIMENT, A QUANTITATIVE CBPR TO RAISE AWARENESS ABOUT THE IMPORTANCE OF HEALTHY SOILS AND OF THEIR HYDROLOGICAL FUNCTIONS

S. BARONTINI<sup>1</sup>, F. BARISANI<sup>1</sup>, E. CURTI<sup>2</sup>, G. GROSSI<sup>1</sup>, M. MARRA<sup>1</sup>, M. PELI<sup>1</sup>, P. VITALE<sup>2</sup>

<sup>1</sup> Università degli Studi di Brescia, DICATAM, Brescia, ITALY

<sup>2</sup> Liceo Scientifico Statale N. Copernico, Brescia, ITALY

Soil health is hydrologically reflected in the water-storing capability and in the reduction of runoff peaks in favour of the aquifers recharge. It is consequence of many factors, but an important role is played by macroporosity, as a source of preferential flow.

Aiming at contributing to disseminate the importance of healthy soils for the society and at highlighting their hydrological functions, we designed the WormEx II experiment, an educational experiment and a citizen-based participatory research (CBPR) performed in high-school classes, in view of attracting students' attention on the hydrological role played by macropores, through the observation of some aspects of earthworm digging activity.

The core of the experiment consists in replicating Charles and Horace Darwin's famous observations on the sinking of stones. We reproduced a couple of wormstones (inspired by that positioned by Horace Darwin at Down House), and we positioned them in the garden of the Liceo Copernico high-school in Brescia in March 2022. Since then many sinking measurements were performed with the participation of high-school and university students, teachers and faculty staff.

The analysis of the experiment is multi-faceted and offers many interpretative keys. Firstly students meet Charles and Horace Darwin's original works on the matter. They go in depth with the text analysis, recognizing both Charles' rigorous epistemological approach based on ample data collection and Horace's attitude at designing an experiment to obtain good quality data. Contextually they deal with the scientific importance of patient practice and long lasting data collection. According to Charles Darwin's definition of «minima», students appreciate how meaningful changes in Nature are mostly given by the reiterate superimposition of minimal ones. They observe aspects of earthworm ecology, regarding their digging activity into relationship with the antecedent meteorological conditions, and recognize the soil attitude at behaving as a low-pass filter of the meteorological variability. Finally, they approach the quantitative treatment of data thus attempting to overcome the qualitative approach of most CBPR activities.

#### 2.11 133574 - Soil and water conservation issues worldwide: from the past to the future

##### IMPACT OF VEGETATION RESTORATION ON CHANGES OF RUNOFF/SEDIMENT AND UNDERLYING MECHANISM ON LOESS PLATEAU

X. ZHANG, R. LI, X. XU, H. YI, Q. TIAN

Institute of Soil and Water Conservation, Northwest A&F University; CAS/MWR, Yangling, CHINA

To improve the ecological environment, China issued a policy of GFG in 1999. Afforestation and revegetation play a prominent role in improving soil properties and controlling soil erosion. A typical catchment was selected to analyze the trends in climate, LUCC, and runoff/sediment from 1960 to 2020, and investigated the role of vegetation restoration in the changes of runoff/sediment in these land-surface processes and the underlying mechanism.

1) Annual precipitation in the area showed a slight decreasing trend over the past 60 years. Landsat-image interpretation showed that, compared to 1980, the area of farmland in 2020 decreased by 46.4%, and that of vegetated area increased by 25.6%. While the average annual streamflow decreased significantly from 35mm in the 1960s to 19mm in the 2010s. The average annual sediment yield dropped from 0.99 billion t to 0.10 billion t over the period.

2) Planting trees and grasses since 1999, significantly affected soil properties. It increased the organic matter content, decreased the soil bulk density, increased the content of >0.25mm water-stable aggregates, enhanced the stability of aggregates, increased the soil porosity, and improved the soil infiltration performance. The structural equation model indicated that soil bulk density, total porosity, and macroaggregate content are the key soil parameters affecting the saturated soil hydraulic conductivity.

4) Budyko's elasticity-coefficient method and fractal theory approach tested that, large-scale ecological restoration since 1999, contributed 66.3% and 81.7% to the change of runoff and sediment yield in the area, respectively. SWAT and the Geodetector tool were further used and found that the explanatory power for the spatial distribution of runoff, is significantly greater for soil properties such as saturated hydraulic conductivity, organic matter, and total porosity, than for surface human activities like increased vegetation cover and climate factors like precipitation changes.

These findings reveal and corroborate that vegetation restoration affects runoff-sediment changes, in essence by improving soil quality and enhancing water storage and retention capacity.

##### REVIEW AND ENLIGHTENMENTS OF SOIL AND WATER CONSERVATION ON THE LOESS PLATEAU OF CHINA IN LAST 70 YEARS

R. LI <sup>1</sup>, Q. YANG <sup>3</sup>, F. WANG <sup>1</sup>, X. ZHANG <sup>1</sup>, C. WANG <sup>3</sup>, H. SHI <sup>1</sup>

<sup>1</sup> Institute of Soil and Water Conservation, Chinese Academy of Science and Ministry of Water Resources,, Yangling, CHINA

<sup>2</sup> Institute of Soil and Water Conservation, Northwest A&F University, Yangling, CHINA

<sup>3</sup> College of Urban and Environmental Sciences, Northwest University, Xi'an, CHINA

The Loess Plateau is an important birthplace of the Chinese civilization. However, this region has become the area with the most serious soil erosion and ecological fragility because of the quick and unreasonable land-use and the population increase. Since the 1950s, a series of major soil and water conservation projects have been implemented, and most of the barren mountains and hills have been covered by vegetation. The annual average amount of sediment delivery of the Yellow River decreased significantly.

According to the main objectives and measures, the past 70 years could be identified as 3 stages. (1) The first stage (1949-1979) was characterized by fortification due to harm. The main goal is to control slope soil erosion, reduce sedimentation yield to the Yellow River, and increase grain production and river safety. After 30 years of efforts, large-scale basic farmland construction and some backbone projects were implemented, which greatly promoted the change of local agricultural basic conditions, as results in improving local people's living level and reducing Yellow River sediment. (2) The second stage (1980-2000) is characterized by small watershed comprehensive management. In this stage, a small watershed was taken as a unit to rationally allocate land-use and measures of soil and water conservation, aimed at improving the rural economy integrated agriculture, forestry, and animal husbandry. (3) The third stage (after 2000) is characterized by ecological restoration. In this stage, GGP (Green for Grain Project) is implemented in which the Chinese government supported farmers to transfer the cropland on the slopes into forests and grassland.

After soil and water conservation of 70 a, remarkable achievements on the Loess Plateau have been achieved, but it is very important to realize clearly that the Loess Plateau still faces severe challenges caused by natural and human activities. Many original factors causing soil and water loss still exist, as well as many new factors arise. Therefore, the tasks of soil erosion control are still arduous.

##### LAND DEGRADATION DUE TO WATER EROSION IN THE CZECH REPUBLIC AND POSSIBILITIES OF CORRECTIVE MEASURES USING STRIP CROPPING AND THE LANDSCAPE CONNECTIVITY CONCEPT

B. SARAPATKA, M. BEDNAR

Palacky University, Olomouc, CZECH REPUBLIC

Water erosion is the most significant degradation factor affecting soil quality in the Czech Republic (CZ), where more than half of agricultural land is at risk. Accelerated erosion is largely influenced by anthropogenic factors, with a substantial increase in the average size of arable land blocks to around 20 hectares (largest in the EU) during the post-war period in CZ due to collectivization, and the removal of almost two-thirds of scattered landscape greenery. As a result of erosion processes, significant changes in the physical, chemical, and biological properties of the studied soils are now documented. These changes affect both production and non-production functions, having an impact not only on the soil environment, but extending to biodiversity and water management. Changes in soil properties, on-site and off-site effects in a productive agricultural area will be presented in this contribution. Addressing this situation requires carefully designed landscape restoration projects and sustainable agricultural systems, to mitigate soil damage, and other environmental components. Based on the modeling of erosion processes and landscape connectivity, we are working on measures that can reduce overall erosion risk and contribute to increased biodiversity. One option is strip cropping. Over a model area of 750 hectares, we will present the effects relating to a reduction in erosion processes for the most common crops, including the application of soil conservation technologies. According to our analyses, this approach can reduce soil loss due to erosion in the studied area approx. three times. This farming system also positively affects runoff conditions and water retention in the area. Non-productive areas are also part of these measures, influencing the enhancement of landscape biodiversity and the protection of water sources. The proposal of such elements, respecting geomorphological conditions and using the connectivity concept, will also be presented in the model area. Addressing these issues is a focus of projects coordinated by the Czech Technological Agency, projects SS02030018 and SS06010290, aligning with EU and CZ strategies.

##### THE FUTURE OF SOIL WITHIN THE CITIES: CHALLENGES AND OPPORTUNITIES FOR THEIR CONSERVATION

J.L. RUBIO

World Association of Soil and Water Conservation-WASWAC, Valencia, SPAIN

In a few decades 80% of humanity will live in cities. Cities will become one of the most important terrestrial ecosystems. This trend is a changing paradigm with important implications that offer the opportunity to design friendlier, more resilient, healthy and sustainable cities. In this context, adequate management and conservation of the urban soils are key elements in the functioning of a re-naturalized city. This will require to develop urban-specific soil ecological knowledge and appropriate management-conservation for soil health and productivity. Urban soils provide a number of important ecosystem services including reduced and delayed storm water and runoff volumes, enhanced groundwater recharge, increased carbon sequestration, urban heat island mitigation, reduced energy demand, improved air quality, additional wildlife habitat and recreational space, improved human health and aesthetical values, opportunity for recreation, exercise, therapy, and education, increased land values and are basic for urban agriculture, among others.

Urban soils can be affected by physical degradation, such as compaction and sealing, which reduces their water-holding capacity. This can lead to increased runoff, flooding, and urban heat island effects, as well as reduced soil fertility and biological activity. Furthermore, urban soils can lose their natural diversity and functionality, as they are often disturbed, contaminated, mixed, or replaced by artificial materials.

Urban soils are unique entities that demand expanding the scope of soil-water conservation, restoration and sustainable management to enhance their agro-ecosystem services as well as improve their resilience and adaptation to climate change. Among these measures, nature-based solutions (NBS) should be considered, with strong priority to the biological component of soil, ecological restoration, improvement of biodiversity, mechanical interventions, structures, prevention of contamination and improving of the physical, chemical and biological properties of the soil.

The incorporation of new and more ecological perspectives in the management and conservation of urban soils will have a crucial and positive impact on the design, management and viability of the green, friendly and sustainable cities of the future.

##### ESTIMATING BIOLOGICAL CONSERVATION MEASURES FACTOR B IN THE CSLE USING GOOGLE EARTH ENGINE

H. SHI <sup>1</sup>, Y. WU <sup>1,2</sup>, B. LIU <sup>3</sup>, Y. WANG <sup>1,2</sup>, M. GUO <sup>1,2</sup>, R. LI <sup>1,2</sup>, J. SHUI <sup>1,2</sup>

<sup>1</sup> Institute of Soil and Water Conservation, Chinese Academy of Science and Ministry of Water Resources, YANGLING, CHINA

<sup>2</sup> Institute of Soil and Water Conservation, Northwest A&F University, YANGLING, CHINA

<sup>3</sup> School of Geography, Faculty of Geographical Science, Beijing Normal University, BEIJING, CHINA

Soil conservation planning often requires estimates of soil erosion at a catchment or regional scale. So far the most widely applied and accepted empirical models are Universal Soil Loss Equation (USLE) and its revised version (RUSLE), Based on USLE/RUSLE, the Chinese Soil Loss Equation (CSLE) was developed with the consideration of soil and water conservation measures, and the cover and management and support conservation factors (CP) in the USLE/RUSLE are divided into three factors, i.e. biological (B) engineering (E) and tillage (T) factors, which make the operation easier for practical applications. The CSLE model describes the main factors based on natural and anthropogenic environmental components. Among the soil erosion parameters, the vegetation cover and biological conservation measures B-factor has been one of the most difficult to estimate over broad geographic areas. In this study, we developed an optimal computational procedure for estimating and mapping the B-factor in the Google Earth Engine (GEE) cloud computing environment using multiple data sources. We evaluated the availability of daily precipitation data (CHIRPS, ERA5, and PERSIANN-CDR data) against the data at national meteorological stations, and calculated the ration of rainfall erosivity over a 24 half-month periods. MOD09GA, Landsat8, and Landsat7 images were used to patch the missing data in the Sentinel-2 imagery, to calculate the NDVI over a 24 half-month period. Based on NDVI data, the pixel-based binary model was applied to compute the vegetation cover, and the average vegetation cover for the 24 half-months period was then derived. Then the B-factor were calculated and mapped based on rainfall erosivity, vegetation coverage, and land use types. We found that the restored high-resolution Sentinel-2 data fit nicely with the 10-m resolution land use data, enhancing the B factor calculation accuracy from the region to the spot level. The B factor computation procedure developed in this study is applicable to various river basin and regional scales for soil erosion monitoring and mapping.

##### REVIEW AND ASSESSMENT OF CHINESE SOIL AND WATER CONSERVATION POLICY

D NING<sup>1</sup>, Q PAN<sup>1,2</sup>, P DU<sup>1,2</sup>

<sup>1</sup> World Association of Soil and Water Conservation (WASWAC), BEIJING, CHINA

<sup>2</sup> International Research and Training Center on Erosion and Sedimentation (IRTCES), BEIJING, CHINA

The new China was founded in 1949. Over the past 75 years, China has continuously adjusted and improved its SWC policy, and formed a policy system containing erosion prevention, erosion control, and technology assistance.

During the 1950s to 1970s, China established SWC administration at the central level, even the SWC Commission of the State Council. In 1957, the State Council released the Provisional Outline of Soil and Water Conservation of the PRC. It's the first legal document of SWC in China. In 1963, The State Council issued the Decision on Soil and Water Conservation in the Middle Reaches of the Yellow River, pointed the Loess Plateau to be the focus area of the state's SWC work.

During the 1980s and 1990s, National SWC Projects have been set up, funded by the central government, to control soil erosion by the way of small watersheds comprehensive control. Three-North Shelter Forest Program came into operation, in the wind-erosion area. In 1991, the Law of Soil and Water Conservation was enacted.

Since 2000, the central government increased investment in the National Soil and Water Conservation Projects and the Three-North Shelter Forest Program. The project of returning farmland to forest or grassland has been implemented.

Since the new century, the area of soil erosion and the amount of sediment discharge in large rivers in China have decreased obviously. The water erosion area increased from  $1.53 \times 10^6$  km<sup>2</sup> in the early of 1950s to  $1.79 \times 10^6$  km<sup>2</sup> in the late of 1980s, then decreased to  $1.09 \times 10^6$  km<sup>2</sup> in 2022. The wind erosion area increased from  $1.88 \times 10^6$  km<sup>2</sup> in the late of 1980s to  $1.96 \times 10^6$  km<sup>2</sup> in the early 2000s, then decreased to  $1.56 \times 10^6$  km<sup>2</sup> in 2022. The change of soil erosion area is not only affected by soil and water conservation policies, but also by population, land use structure, economic development level and other factors.

##### SOIL AND WATER CONSERVATION VS SOCIETY AND WORLD CONSERVATION: THE EARTH BENEATH OUR FEET BEARS OUR FUTURE

F. WANG<sup>1</sup>, R. LI<sup>1,2</sup>, W. GE<sup>1,2</sup>, J. HAN<sup>1,2</sup>, S. SHI<sup>1,2</sup>, H. CHEN<sup>1,2</sup>

<sup>1</sup> Northwest A&F University, Yangling, Shaanxi, CHINA

<sup>2</sup> Institute of Soil and Water Conservation, Chinese Academy of Sciences and the Ministry of Water Resources, Yangling, Shaanxi, CHINA

Soil-based system is the fundament of human development. The nutrient depletion and soil loss are hundreds and thousands of times faster than the formative process of soil and its ecosystem. There were many ancient civilizations, such a Maya, Indus and Easter Island, collapse because or partly because of the degradation of soil-based system.

The soil erosion and its various impacts on natural resources, environment and human health has been noticed and approved by the development of modern science and technology mainly in last century. The soil and water conservation evolved greatly from prevention and control of water and wind soil erosion for growth, to disaster mitigation for agriculture and living conditions, and to nature-based solution for better ecosystem services and wellbeing of human, and the adaptation to climate change. We must accept the truth that the soil is utmost element on the earth because of the soil has already been playing an irreplaceable role in our plenary. It is reasonable to treat soil and water conservation as society and world conservation from now on.

It is worth to gain some knowledge on the important of soil and water conservation in a glance of 100 years of soil sciences, but it is still far not enough to solve many challenges of soil-based system with active and positive soil and water conservation mainly because of the awareness and wisdom of people and communities. It is time to analysis the conditions relating to soil erosion and UN SDGs carefully, and to find the promising technologies and approaches with local suitability for demonstration, extension and updating in various conditions and objectives based on the past lessons of soil and water conservation in last century from successful cases worldwide.

#### CHARCOAL BURNING – A NEGLECTED SOIL-FORMING FACTOR IN CULTURAL LANDSCAPES

A. RAAB, A. SCHNEIDER, A. BONHAGE, T. RAAB

Brandenburg University of Technology Cottbus-Senftenberg (BTU), Cottbus, GERMANY

About 20 years ago, the systematic archaeological study of remains from pre-industrial charcoal burning, known as Relict Charcoal Hearths (RCHs), commenced in open-cast lignite mines in South Brandenburg, Germany. In the Jänschwalde open-cast mine alone, more than 1,500 RCHs have been documented through archaeological excavations, with hundreds of kilograms of charcoal sampled, offering a unique foundation for future research. Expanding geopedological research to other regions in Germany and the Northeastern USA has significantly augmented our understanding of the formation, properties, distribution, and function of RCH soils. Soil profiles on RCHs display distinct morphology, characterized by profound charcoal-rich technogenic substrate layers. These layers demonstrate heightened carbon content and distinctive physical and chemical properties, including relatively low bulk density, high porosity, increased plant-available water content, reduced thermal conductivity, and variations in cation exchange capacity and nutrient status. Utilizing LiDAR-based high-resolution Digital Elevation Models (DEMs) allows for the mapping of RCH sites due to their unique relief signature. This landform fingerprint, coupled with findings from RCH soil profiles and catenae, contributed to deriving a morpho-genetic catalog for RCH classification applicable in various contexts. Employing machine learning-based remote sensing methodologies shows promise in comprehensively assessing the extent of charcoal burning legacies on a landscape or catchment scale, including aspects such as soil carbon sequestration and soil moisture dynamics. Our presentation will highlight the primary outcomes of our extensive study on RCH soils and unveil recent research findings. While RCH research has made considerable progress in the last five years, the understanding of ecological legacies remains limited. Hence, there is a need for further interdisciplinary and integrative ecosystem studies, requiring expertise in both archaeology and pedology as fundamental prerequisites.

### REVISITING PEDOLOGICAL CONCEPTS OF 'TIME ZERO' AND 'MATURITY' IN SOILS OF ARCHAEOLOGICAL STONE-WALL BENCH TERRACES

D. ITKIN

<sup>1</sup> Soil Erosion Research Station, Ministry of Agriculture & Rural Development, Rishon LeZion, ISRAEL

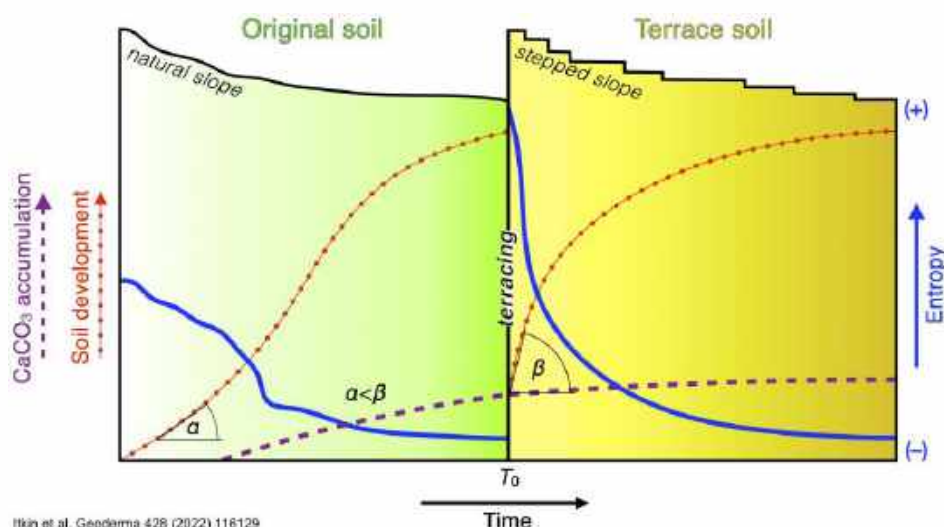

<sup>2</sup> Department of Environmental Science and Technology, University of Maryland, Maryland, USA

Archaeological stone-wall bench terraces cover about 85,000 km<sup>2</sup>, most of which are found in temperate and arid climatic zones. Many terracescapes are obscured by newer land usages. Terrace soil (also 'fill material') may be found either exclusively at the forefront of a terrace, throughout its whole space, or at any setting in between. These soils develop through deposition of locally human-transported soil, inheritance of aggregates from their parent soil, thickening (soil aggradation) and neopedogenesis that involves structure development, reaggregation with little occurrence of organic matter, and frequently low levels of lessivage and CaCO<sub>3</sub> redistribution.

Early stages of terrace soil development occur chaotically and much faster than natural soils, thus different from classical soil models and pedogenic concepts of 'time zero' and 'maturity'. 'Time zero' (T<sub>0</sub>) is when a catastrophic event is completed and new material forms at the land surface. However, the presence of ex situ mature constituents in terrace soils, including richer biodiversity compared to natural soils' T<sub>0</sub>, contradicts the applicability of the time zero theory. The forming of terrace soils also challenges the 'space-time continuum' model that argues that no soil is present before T<sub>0</sub>.

There are two possible ways to consider the age of terrace soils. The notion that ex situ soil is aggregated as legacy material in terrace soils implies that it is composed of older material than the terrace itself. Another way to evaluate the age of terrace soils is by the 'geomorphic surface' concept, in which the age of a geomorphic surface and its soils are regarded the same.

Soils can be described as an open system driven by external factors toward 'pedogenic order', hence minimum entropy and highest energy in the soil system. Therefore, the development of natural soils is characterized mainly by an entropy decrease. In contrast, the first formation stage of terrace soils is chaotic and dissipative, thus characterized by an entropy increase.

#### SEARCHING FOR BRUSSELS' LATE MEDIEVAL GARDENS: GEOARCHAEOLOGICAL RESEARCH IN THE ANCIENT WETLANDS OF THE SENNE VALLEY (BELGIUM)

Y. DEVOS<sup>1</sup>, C. PÜMPIN<sup>2</sup>, D. BRÖNNIMANN<sup>2</sup>, L. VRYDAGHS<sup>1</sup>, M. ALONSO-EGUILUZ<sup>1</sup>, K. ISMAIL-MEYER<sup>2</sup>

<sup>1</sup> Vrije Universiteit Brussel, Archaeology, Environmental Changes & Geo-Chemical Research Group (AMGC), Brussels, BELGIUM

<sup>2</sup> University of Basel, Integrative Prehistory and Archaeological Science (IPAS), Basel, SWITZERLAND

Historians advocate that, alongside cereal cultivation and animal husbandry, horticulture was one of the key elements in the development of the city of Brussels. According to them, during the late Middle Ages (13th-15th centuries) part of these horticultural activities were concentrated in the marshy areas of the Senne Valley on the north side of Brussels (Charruadas & Deligne 2007). Archaeologically, however, these gardens remained undiscovered until an emergency intervention in 2014 in the heart of the ancient wetlands.

At that occasion, archaeologists excavated on the site of Rue des Boîteux/Rue d'Argent a buried late medieval Anthrosol (Dark Earth) on top of a thick Holocene peat layer. As diagnostic features such as fences, implement marks or drainage ditches were not observed, confirmation of its identification as being the remains of an ancient garden required an integrated geoarchaeological approach.

The present contribution discusses how the geoarchaeological study permitted to identify this anthrosol as a late medieval garden. We will hereby focus on how an in-depth study of soil thin sections, involving a variety of specialists, contributes to document a series of ancient horticultural practices in urban wetland areas, including drainage, soil working and manuring.

#### THE EFFECT OF VOLCANIC ACTIVITY IN ANCIENT HUMAN POPULATIONS: THE CASE OF COLOMBIA AND MEXICO

E. SOLLEIRO-REBOLLEDO, A. TRIANA-VEGA, T. GARCIA-ZEFERINO, S. SEDOV

Instituto de Geologia, UNAM, Mexico, MEXICO

Volcanic activity has strongly affected human societies over time. Some have been resilient to an explosive eruption, while others could not recover after volcanic activity. Additionally, soils or volcanic materials could be further used, representing a resource for agriculture or construction. This work presents two study cases from Colombia and Mexico, which were affected by volcanic phenomena. In the case of Colombia, the archaeological site at Aguazuque, Savanna de Bogota, shows a long-term human occupation during the Holocene (between 8,000 and 2,500 BP), which causes complex interactions with the landscape. In particular, the studies have documented occupation in Aguazuque (a pre-ceramic site). This site is on a high plateau area (2600 masl), surrounded by sandstones. The geoarchaeological survey reveals the use of re-worked soils with similar characteristics to Andosols, which differ from those around the site. They are dark brown but compact with an angular blocky structure, properties associated with vertic processes. However, they are beneath a 50 cm-whitish sediment of fine volcanic ash. This material was probably used for the construction of the site, which suffered pedogenesis or deep transformation by human manipulation. On the other hand, we studied the Cerro del Teúl area in western Mexico, where the archaeologists found a 10 cm white ash covering the infills of the main structures. This ash was characterized geochemically and petrographically and showed a great affinity to the Jala eruption of the Ceboruco volcano, which occurred around 1000 AD. This event did not cause the site's abandonment, but the inhabitants used the volcanic material for construction, immediately after the ash fall. Consequently, the Teúl site reflects a re-occupation and adaptation of new conditions.

<sup>5</sup> Joukowsky Institute for Archaeology and the Ancient World, Brown University, Providence, USA

<sup>6</sup> Department of Earth, Environmental & Planetary Sciences, Providence, USA

A land unit map was created for an area of 78 km<sup>2</sup> in western central Sardinia centered on the archaeological complex of S'Urachi that was first built in the Bronze Age and that remained continuously occupied until the early Roman Imperial period. The site of S'Urachi is located ca. 15 km inland from the west coast of Sardinia in the northern part of the Campidano graben. The aim of this land evaluation was to assess the suitability of local soils for land utilization types (LUTs) in late prehistory and the early historical period, broadly covering the 1st millennium BCE, that largely rely on low-technology arable farming. In addition, we also aimed to identify unsuitable land units that could still be employed for pasture or left fallow. The definition of LUTs used derives from cereal remains and the faunal assemblage retrieved during the excavations at S'Urachi and from the study of pollen obtained from a core drilled in a low-lying area ca. 3.5 km SW of the site. These archaeo-environmental data have been therefore included in the approach to present-day land evaluation, that was carried out employing the standard FAO (1976) guidelines. The land characteristics that were taken into consideration were slope, drainage class, soil texture, stoniness, rockiness, and soil type all thought to be determining factors in 1st millennium BCE land use and that could still be determined today. The result of this archaeological land evaluation is the first approximation of a land unit map.

#### **PALAEOSOLS OF SARDINIA: NEW EVIDENCE FROM GEOARCHAEOLOGICAL AND GEOCHRONOLOGICAL RESEARCH AT THE CENTRAL-NORTHERN SITE OF PUNTA FERULOSU (BONORVA, SS)**

G.B. MARRAS<sup>1</sup>, F. SULAS<sup>2</sup>, G. ROBIN<sup>3</sup>, A. SCRIVNER<sup>4</sup>, L.C. SKINNER<sup>4</sup>

<sup>1</sup> University of Cambridge - Department of Archaeology, Cambridge, UNITED KINGDOM

<sup>2</sup> University of Gothenburg - Department of Historical Studies,, Gothenburg, SWEDEN

<sup>3</sup> University of Edinburgh - School of History, Classics and Archaeology, Edinburgh, UNITED KINGDOM

<sup>4</sup> University of Cambridge - Godwin Laboratory for Palaeoclimate Research, Department of Earth Sciences, Cambridge, UNITED KINGDOM

Despite being the second largest island of the Mediterranean and bearing dense and monumental evidence of prehistoric human occupation since the onset of the Middle Holocene, the Holocene soil-environmental history of Sardinia remains poorly understood. Much palaeo-environmental research has focused on the Sardinian coastline, exposing the impact of changing climate on coastal geomorphic systems and late Holocene communities. This leaves a significant gap in the understanding of palaeoenvironmental conditions on the rugged uplands away from the sea and their interplay with dense prehistoric settlements.

To shed new light on these issues, high-resolution field and laboratory geoarchaeological analyses examined the upland landscape surrounding the archaeological site of Punta Ferulosu, Bonorva (SS), an area which was densely occupied by Final Neolithic and the Copper Age societies (6000-4000 BP). Sedimentary and buried soil archives were investigated in the field with lithological and pedological analyses, and sampled for physicochemical, micromorphological, and geochronological laboratory analyses. These have allowed the identification of a reddish buried soil with a well-developed cambic horizon (with fine clay coatings) whose evidence only survives beneath the prehistoric stone structures of the site dated to ca. 5000 BP. This buried soil can be associated with pedogenesis under warm and wet climate conditions that promoted dense vegetation cover and slope stability over the Early-Middle Holocene. Geochronological analysis integrated with micromorphology of a nearby sedimentary archive has identified the source of the sediments from the erosion of the buried Cambisol and provided the first radiocarbon-dated geological evidence, ca. 6000 BP, of Final Neolithic-Copper Age landscape transformation.

The new sedimentary and buried soil record starkly contrasts the modern-day poorly developed Leptosol found across the landscape and contributes valuable insights into palaeopedological records and the history of human-environment interactions in Sardinia, pre-dating the anthropogenic impacts on the island's landscape.

The long-inhabited Central European lowlands have exposed to significant erosion since prehistoric times, primarily due to deforestation and agricultural practices, leading to colluvium formation and erosional features. Infilled erosional gullies, particularly near abandoned settlements, may offer insights into landscape changes and settlement evolution. Our research delved into the complex interaction between human settlement, land use and the environment in prehistoric times, focusing on pedosedimentary record found within an infilled loess gully on the Predmostí u Prerova site (Czech Republic). We employed a combination of geoarchaeological and palaeoecological methods such as physico-chemical analysis, soil micromorphology, OSL and C14 dating as well as palynology and anthracology, along with archaeological geophysics and extensive development-driven excavations, to examine erosion, soil formation and settlement histories. By combining geophysics and excavation results, we investigated settlement and land-use patterns, correlating these with the environmental and pedosedimentary record of an infilled gully. The incision of the gully represented initial phase of erosion at this site. Formed before 2300 BC, it is among the oldest in the region, likely triggered by Late Neolithic land use. The study further identified cyclical patterns in both population dynamics and the pedosedimentary record, likely linked to changes in settlement and land-use practices. Periods of reduced or absent population pressure led to surface stabilisation and pedogenesis. In contrast, times of increased anthropogenic impact were associated with the erosion of surface soils and deeper erosion, followed by sediment accumulation in the gully. Our findings indicate four main erosion phases correlated with primary settlement peaks: the Early Bronze Age (2300–1600/1500 BC), the Young/Late Bronze Age (1500–900 BC), the Hallstatt period (900–400 BC) and the La Tène period (400 BC–50 BC/1 CE). Future research on additional erosion gullies could confirm and refine these findings and determine whether this is a regional pattern.

**MICROMORPHOLOGY OF URBAN DEPOSITS: FROM IRON AGE CITIES TO MEDIEVAL DARK EARTH (FRANCE)**

C. CAMMAS

INRAP, Paris, FRANCE  
UMR 5140, Montpellier, FRANCE

Urban archaeology encompasses a great diversity of archaeological stratifications and excavations of various sizes. One of its goal is to restore the organisation and the evolution of past towns and cities as well as their status. Over the last few decades, micromorphological analyses provided new archaeological data and helped to reconstruct past anatomy and activities of sites. In France, we carried out analyses on numerous French urban archaeological sites dating from Iron Age, Roman Period and Early Middle Ages on the French territory (Northern and Southern France, mediterranean climate and oceanic to continental zones).

Results of the analyses include the identification and sedimentary characterisation of various type of activities (trampling, grinding, animal enclosure, fire-related activities...) and types of spaces (courtyard, traffic area, living quarters, different types of Dark earth...) and their evolution through time. They reveal cultural and geographical specific aspects, such as building materials, construction / refection rhythms, and use of space.

The repetition of studies uncovers methodological issues between micromorphological data and archaeological results. It leads to propose a theoric framework, which help reconstructing past activities and organisation in the towns / cities, and facilitate the pluri disciplinary exchanges.

Moreover the results of these studies go beyond the archeological field of study as they provide information on the nature and the pedological functioning of urban soil and its variability, which are of interest for current research on urban soils.

<sup>3</sup> EDITORIAL BOARD-SCIENTIFIC CULTURE REVIEW, KEY RESEARCH INSTITUTE OF YELLOW RIVER CIVILIZATION AND SUSTAINABLE DEVELOP

Brazil, a nation endowed with unparalleled biodiversity and a rich cultural variability, places a paramount emphasis on sustainable development. At the heart of this commitment lies the environmental licensing process designed to harmonize economic progress with environmental and cultural preservation. In navigating this intricate landscape, two critical components—rescue archaeology by soil-drilling grid—emerge as pillars. The environmental licensing process is meticulously attend both federal and state legislation to uphold rigorous environmental standards. A soil grid use a Krige methodology in order to obtain the best sample for drilling. Kriging can be understood as linear prediction or a form of Bayesian Inference. It assumes that nearby points in space tend to have more similar values than points that are further away. The Kriging technique assumes that data collected from a given population are correlate in space. At its core, this process seeks to evaluate the potential impacts of proposed projects, ensuring adherence to environmental regulations before granting the necessary permits for construction or operational activities. The journey through the licensing process involves EIA/RIMA is running a Rescue Archaeology Process leading by IPHAN/INAHH- Instituto do Patrimônio Histórico Artístico Nacional which is the main governmental institution for safeguarding Brazil's Cultural Legacy. Such proactive practice of rescue archaeology is a testament to Brazil's commitment to preserving its rich archaeological cultural heritage. Archaeologists jointly with geologists employ drilling techniques to analyse soil composition, stability, and contamination levels in and around the project site. The utilization of soil-drilling grid is not merely a reactive measure; it is a proactive strategy to identify and address potential environmental risks before they materialize. By integrating soil drilling into the licensing process, regulators and project developers alike, become stewards of the environment, ensuring that development initiatives proceed with an acute awareness of their environmental and culture heritage footprint. In order to clarify better such process, a study cases will be present as a symbiosis of cultural heritage preservation and environmental responsibility.

### THE MISSING FEATURES OF THE PO PLAIN – A CASE FOR ENVIRONMENTAL MAGNETISM AND WHAT IT CAN TELL ABOUT FORMATION PROCESSES AND ENVIRONMENTAL SETTINGS OF FEATURES AND SITES

J. KAINZ <sup>1</sup>, G. STRAPAZZON <sup>2</sup>, A. BETTO <sup>3</sup>, C. MARASTONI <sup>4</sup>

<sup>1</sup> University of Vienna, Vienna, AUSTRIA

<sup>2</sup> Independent Researcher, Schiavon, ITALY

<sup>3</sup> ArcSAT snc di Valente Vincenzo e C., Padova, ITALY

<sup>4</sup> Soprintendenza Archeologia, Belle Arti e Paesaggio of Cremona, Lodi and Mantova, Mantova, ITALY

Geophysical methods, especially magnetometry due to its applicability, are some of the most used and effective tools for monitoring, controlling, managing and investigating buried archaeology. Alluvial settings are challenging environments for geophysical methods and therefore the Soprintendenza Archeologia, Belle Arti e Paesaggio of Cremona, Lodi and Mantova wanted to assess the use of magnetometry and ground penetrating radar (GPR) across sites from the Bronze Age to the Middle Ages in the central Po Plain, Northern Italy.

Aerial photographs indicated an abundance of archaeological features across the sites. GPR corroborated these when ground conditions permitted however less by magnetometry. Two sites with similar archaeology, however magnetically visible and invisible, were therefore examined for their magnetic and chemical properties.

Environmental magnetism allows examining soils by their magnetic characteristics, such as the type of magnetic mineral, their concentration and domain states. These characteristics directly relate to a soil's formation and post-formation processes, the parent material and prevailing environmental conditions and therefore vital insights into the environmental history of a feature and its site.

Magnetic susceptibility, magnetic hysteresis, isothermal remanent magnetisation and back-field remagnetisation curves alongside pXRF allowed identifying the magnetic and chemical characteristics of the natural and archaeological soils. This enabled differentiating the natural and archaeological soils through their magnetic minerals, their concentration and magnetic domain states while the magnetic unmixing allowed examining the contribution of the individual magnetic components. Alongside pXRF this allowed characterising the natural and archaeological soils of the sites and features and their similarities and dissimilarities providing vital insights into their formation and post-formation processes.

Identifying the magnetic and chemical properties allowed addressing the different magnetic (in)visibility at the two sites while importantly providing vital insights of the formation and post-formation processes at the sites and their archaeological soils. Such allowed for a better understanding and future application of magnetometry in the region while also providing vital insights into environmental changes at the two sites by using environmental magnetism.

#### PROJECT SIGNATURE: APPLICATION OF SOIL SCIENCE TECHNIQUES COMBINED WITH REMOTE SENSING IN ARCHAEOLOGICAL RESEARCH

S. NEOGI<sup>1</sup>, F. CONESA<sup>1</sup>, H. ORENGO<sup>1</sup>

<sup>1</sup> Institut Català d'Arqueologia Clàssica, TARRAGONA, SPAIN

The potential of satellite imagery as a technique of archaeological site prospection, particularly in the Middle East, has been widely recognised since the beginning of the 21st century (e.g., Donoghue, 2001; Donoghue et al., 2002; Philip, Donoghue, et al., 2002; Pournelle, 2003). However, while traditional extensive desk-based survey methods have proved effective in locating the morphologically distinctive nucleated tell sites characteristic of settlement in the Bronze and Iron Ages, they have been less successful in recognising the smaller, pastoral, dispersed settlements common during prehistoric and Graeco-Roman and Medieval occupation – especially in landscapes where mudbrick was the main building material and/or where topographic features have been reduced by ploughing. Many such sites can only be distinguished from background soils by differences in soil reflectance (colour, texture). While multispectral satellite imagery can reveal areas of differential reflectance, not all such features are sites, and the relationship between surface reflectance and the composition of archaeological deposits in different environments is poorly understood. This paper presents the scopes of the project SIGNATURE—an ongoing MSCA project intends to combine big Earth Observation data, machine learning and geoarchaeological signatures of anthropogenic soils in high-performance computational workflows to push forward our capabilities to identify, characterise and protect endangered cultural soilscapes. This paper shows initial ideas about addressing this gap by investigating and comparing the field-observed and image-derived reflectance properties of the soils/sediments from a sample of archaeological sites, of different types, located from several geomorphological units of the Middle East, India and Spain thus increasing the ability of researchers to identify anthropogenic despoils when reliant upon satellite imagery.

<sup>3</sup> University of Miskolc, Department of Prehistory and Archaeology, Miskolc, HUNGARY

<sup>4</sup> University of Köln, Department of Prehistory and Archaeology, Cologne, GERMANY

Relatively little is known about the natural soil properties of the Middle Bronze Age sites and their surroundings in Bükkkalja. It is hoped that diagnostic soil analyses will help us to better understand the selection characteristics of the Bronze Age communal area.

Our study involved the preparation of a diagnostic soil map of a Middle Bronze Age tell and its surroundings in the Bükkkalja area. A soil survey of the area was carried out between 2023-2024, resulting in a precision-scale digital soil map. During the survey, soil horizons were sampled from several different soil profiles. The soil classification followed the guidelines of the WRB system.. A full physical and chemical analysis of the soils in the sampling area was conducted after processing the samples. In addition to the soil analyses, a full geospatial and topographic analysis was also carried out.

In the light of the results, it can be concluded that there is a correlation between certain soil types and the location of the plots. In addition to the diagnostic results obtained, we can also observe the impact of the human activity on the environment.

**INCLUDING SOILS – WORKING TOWARDS KNOWLEDGES, ACTIONS AND VALUES OF SOIL CARE THROUGH EXPERIMENTATION IN RESEARCH, EDUCATION AND BROADER SOCIETY.**

D. STOMPH<sup>1</sup>, G. BONGIORNO<sup>2</sup>

<sup>1</sup> Cultural Geography group, Wageningen University, Wageningen, THE NETHERLANDS

<sup>2</sup> Soil Biology group, Wageningen University, Wageningen, THE NETHERLANDS

Soils often go unnoticed and remain largely under-recognised, especially in their complexity and plurality. This is true for society at large, but also for students and scientists who regularly come into contact with soils. In this paper, as a cultural geographer and a soil biologist, we challenge our ongoing engagements with soils by foregrounding how we may know what soils need. We critically inquire how soils' needs may inform our practices as researchers and what this means for our work with (soil science) students and people who are not scientifically bound to soils. In this inquiry we take inspiration from scholars working on care, the critical zone and relational thinking. This paper bridges both our experiences in working with soils in research, education and beyond to illustrate the (dis)connections between our diverse practical and theoretical engagements with soils. We share work we have done together and individually, and how - through this work - we came to similar insights and concerns about where soils and specifically knowledges and research engagements on soil health are heading.

Taking inspiration from these insights, we experiment with redirecting our work on soil health by trying to reach out to other practitioners, scientists and artists working with and fostering soil health. In this experimentation we centralise that soils do not need humans as much as humans need soils. This insight is humbling and at the same time makes reciprocal engagement with soils inherently troublesome, because it raises dilemmas about what types of human engagement with soil might be just.

Our experiences and reflections illustrate that ongoing work attempting to include soils (and the people who work with them) in all their plurality is generative and therewith promising for the futures of soils' wellbeing. Simultaneously, the work taught us how distant much of the scientific and didactic engagements with soils are from recognising soils as affective beings, as vibrant webs of life-and-matter which are continuously co-becoming.

##### FOR AN ECOLOGY OF WELCOME. THE AGROECOLOGICAL APPROACH OF FATTORIA PIANETA TERRA (MILAN, ITALY)

V. CAPOCEFALO<sup>1</sup>, G. SALI<sup>2</sup>, P. DE MARINIS<sup>3</sup>

<sup>1</sup> Department of Agricultural and Environmental Sciences - Production, Landscape, Agroenergy, University of Milan, Milan, ITALY

<sup>2</sup> Department of Agricultural and Environmental Sciences - Production, Landscape, Agroenergy, University of Milan, Milan, ITALY

<sup>3</sup> Department of Agricultural and Environmental Sciences - Production, Landscape, Agroenergy, University of Milan, Milan, ITALY

The agroecological paradigm aims to restore the conditions which have permitted to agroecosystems in the past to function properly with a small amount of external antropogenic inputs. Agricultural landscape has been deeply affected by conventional practices: homologation, trivialisation and, less frequently, maizification are the terms used to define the impoverishing process suffered by it. In particular, these labels stress the removal of key landscape elements (e.g. hedgerows) fundamental for the connectivity between the agroecosystems and the wider ecosystems in which they are located.

Soil stands at the core of the transformation of agrarian production. Indeed, this deeply affects the health conditions of agroecosystems. Therefore, paying attention to and caring of the soil means not only ensuring its productivity today, but also preserving a common good in the long run. In order to gain the purposes of the agroecological transition, scientists and practioneers have cooperated to produce transdisciplinary and localized knowledge. Nowadays cultural and institutional dimensions are increasingly important to understand how to intervene effectively within the different territorial contexts.

Fattoria Pianeta Terra (Milan, Italy) has been developed starting from these premises, with the purpose to create a large community capable of taking care of a rich and complex portion of territory located at the eastern edges of the Municipality of Milan. The project aims to create a multifunctional place, a renovated old farmstead and its surrounding fields, to welcome a community for minors.

In addition to ensuring local and high quality food production, the project intends to restore also other the ecosystem services, in particular the regulating and cultural ones. In order to pursue this objectives, agroecological practises will be implemented as well as various social farming and craft activities. Fattoria Pianeta Terra involves several public, private and third sector actors, with a long experience in regenerative practices, willing to not just imagine, but rather concretely build, transformative pathways for more just and sustainable futures.

Our proposal is addressed to share the experience of Oltreterra art project, where contemporary art was a mean for connecting aesthetics, art history, science, local history, soil knowledge, nature care.

Started in 2023, Oltreterra art project is an interdisciplinary contemporary art project, focused on the artistic experimentation on the ancient Sienna pigment. The artist Samantha Passantiti, for this project, made a cycle of artworks using the same pigment used since the 13th century, taking it from the same area where it was extracted originally. She went to the quarries – now abandoned - placed in the country of the Amiata Mount, between the cities of Grosseto and Siena, in order to take the original earthy matter of the pigment. Throught this material, the artist experimented the tradition of natural Sienna pigment, very important in the medieval art history, on the field of contmporary art, according to her usual visual language. By this way, Passaniti, deepening her personal research on natural elements in art practice, contributed to renew sustainability awareness. Moreover, also to enhance forgotten places throught the history of soil use.

Indeed, together with the main artistic activity, Oltreterra, thanks to its interdisciplinary identity, has been supported by several partners, as art musuems, natural history museums, scholars specialized in geology and ecology, pro-environment associations, citizen unions. The project, during its year-long duration, organized a lot of different events, such as art shows, lectures, workshops, tours in nature. In each case, practicing an inclusive approach and ever involving a different kind of public.

Oltreterra experience has been collected in a final editorial project, including contributions by humanistics and scientists. So, we would like to promote both a very actual way of conceiving art projects and the importance of topics related to ecological practices in art-making, soil knowledge, sustainability.

**CARING FOR SOILS REQUIRES CARING FOR FARMERS: A REFLEXIVE EXPERIENCE OF THE AFFECTIVITY INVOLVED IN THE FARMER'S RELATIONSHIP WITH THE SOIL.**

L. RICHELLE

UMR ECO&SOLS - IRD (Institut de Recherche pour le Développement), Montpellier, FRANCE

Agriculture is a human practice steeped in relationships with non-human entities. The world's agrobiodiversity and the heterogeneity of human societies have been shaped by these relationships, which can be understood in several dimensions (material, spiritual, social, cultural, sensitive, affective, etc.). Farmers' relationships with soils are multiple and singular. Farmers know their soils personally. When it comes from previous generations, the transmission of this knowledge through farming fosters a personal relationship with the soil. Scientific approaches such as ethnopedology or agroecology give attention to farmers' soil knowledge, but the affective dimension of this knowledge is often missing. One reason may be that addressing personal intimacy is delicate and requires mutual trust. Scientific research should not have to reach every level of human-soil intimacy, but affectivity has been neglected and crushed by the agro-industrial model promoted by agronomic sciences. This denial has left a wound partly responsible for the farmers' current suffering. Alternatives to this model are opportunities to give space again to this affectivity. Accounts from farmers involved in transformative pathways reveal the joy of re-experiencing a personal relationship with the soil and attachment to the land through soil care practices. Supporting and accompanying transformative pathways in agriculture requires also taking care of this affective dimension. Transdisciplinary approaches can allow, in the same movement, both to include the affective dimension in understanding farmers' knowledge and, through a reflexive approach, to highlight the affectivity also present in scientists' relationship with soil and farmers. The experience presented here results from a transdisciplinary research dedicated to collaborative soil health assessment in the Cordoba region of Spain. This collective learning process was an opportunity to learn from farmers and approach their personal relationship with soil. The hypothesis presented here is that considering the affective dimension of agriculture in knowledge dialogue, can significantly facilitate mutual understanding and promote the elaboration of common perspectives between scientists and farmers on how to take care of soil.

##### LANGUAGE OF SOIL

A. TOLAND<sup>1</sup>, K. KRZYWOSZYNSKA<sup>2</sup>

<sup>1</sup> Bauhaus-Universität Weimar, Weimar, GERMANY

<sup>2</sup> University of Oulu, Oulu, FINLAND

Soil protection is a quintessential ‘wicked problem’ of our times. Soils are situated at the nexus of interconnected social, cultural, and environmental crises. Caring for soils urgently requires a transdisciplinary approach. Transdisciplinarity, however, does not just happen. Researchers from different disciplines and backgrounds need time and support structures to develop a shared language for transdisciplinary soil research. This is the objective of an innovative new publication project initiated by Anna Krzywoszynska and Alexandra Toland, co-chairs of IUSS Commission 4.5 on the History, Philosophy and Social Science (and Arts) of Soil Science. Still in the early stage of realization, the book project aims to establish a rich foundation for wide-reaching and long-term transdisciplinary collaboration on soil research. It does so by building an in-depth glossary of the “language of soil” and creating relationships between disciplines via author community-building. The book production is a fully transdisciplinary process. The proposed publication includes over 100 participants from academia and civil society, with whom the editors will map the field of transdisciplinary soil research. In the process, the editors will identify key boundary objects as introduced by sociologists Susan Leigh Star and James R. Griesemer (1989): concepts, methods, tools and practices which, while they are interpreted differently, by different groups, nonetheless allow members of different disciplines to talk and work together. The Language of Soil – A Handbook for Transdisciplinary Soil Research is proposed as a unique physical and online open-access collection of concepts and tools for transdisciplinary collaboration in soil research, addressed at scholars and students of social sciences, humanities, arts and natural sciences interested in soils; soil practitioners; transdisciplinary researchers; soil educators: communicators; and policy makers. Its objectives are strongly in line with the overall remit of IUSS Division 4. The book will help will increase the recognition of and engagement with the IUSS across disciplines, working to help establish the „soil humanities“ as an important field of inquiry within transdisciplinary soil research.

##### SOIL AS MEDIUM: EXAMINING HOW SOILS ARE MADE KNOWABLE, SENSABLE AND RELATABLE ACROSS FIELDS

N.S. VAAGE

<sup>1</sup> Department of Art and Media Studies, NTNU, TRONDHEIM, NORWAY

<sup>2</sup> Division for Journalism and Creative Media Studies, Nord University, LEVANGER, NORWAY

<sup>3</sup> NOBA - Norwegian Bioart Arena, ÅS, NORWAY

Soils are challenging entities to understand and relate to: consisting of organic and inorganic compounds, conceived as inert matter or living ecosystems, hidden beneath more or less accessible surfaces, from concrete and sea beds to agricultural fields. The Norwegian Research Council project Anthropogenic Soils: Recuperating Human-Soil Relationships on a Troubled Planet (SOILS, 2022-2028) seeks to examine existing soil knowledges and relationalities, with focus on anthropedogenetic processes and remediation practices towards soils that are depleted or polluted, endangered or dangerous. This paper emerges from the author's PI role in the SOILS work package Experiential Soils, and from the question of how soils can be accessed and engaged with, artistically and phenomenologically.

Philosopher Marshall McLuhan's slogan "the medium is the message" (2001, p. 7) has been mobilised by scientists in discussions of the biological medium of water (Frenkel-Pinter et al. 2021). What does it mean to consider soil as a medium? This paper departs from the established idea of soil as a growth medium for plants and fungi, taking this as a starting point for considering how soils are made knowable, sensible and relatable across fields. The paper draws upon perspectives from media studies, art, postcolonialism, geopolitics and indigenous knowledges in addressing different senses in which soil can be considered a medium. Engagements with soils are also mediated through the various technologies with which we perceive and analyse soils. Finally, the concept of soil remediation is considered through the interlaced lens created by these multiple meanings of soil as medium, exploring how this lens might assist in rethinking conceptions of good soil, soil care, and soil health.

##### ANTHROPOGENIC SOILS: COLLABORATIVE ENVIRONMENTAL HUMANITIES OF SOIL RECUPERATION

U. MÜNSTER

University of Oslo, Oslo, NORWAY

This paper presents the multidisciplinary research project Anthropogenic Soils: Recuperating Human-soil relationships on a Troubled Planet, based at the University of Oslo as a collaborative experiment for studying soils in the Anthropocene. The project studies the ways people in different parts of the world have invented, practiced, and imagined ways of recuperating soil health. We argue that soils need to be conceptualized not as natural resources to be exploited, but as anthropogenic, as lively and dynamic natural-cultural composition responsive to human recuperation and healing. The project combines studies of repairing contaminated, toxic, and depleted soils in different parts of the globe –from South Asia to Norway and the Arctic –as well as artistic and multimedia research into the ways in which Indigenous writers and artists offer alternative modes of relating to soils, and for building possible future of earthly survival. Closely collaborating across the humanities, social sciences arts and life sciences, SOILS combines ethnographic, multispecies and praxiographic methodologies with speculative and artistic research to generate new knowledge about emergent human-soil relations.

##### SHAPING SOIL LITERACY: UNRAVELING PARADIGMS IN EDUCATION FOR SUSTAINABLE HUMAN-SOIL RELATIONS

C. RAMEZZANO, V. TASSONE

Wageningen University & Research, Wageningen, THE NETHERLANDS

The global soil crisis presents a significant threat to socio-ecological sustainability, demanding a re-consideration of the paradigms that shape soil education. Paradigms are normative assumptions describing how we understand the world, make sense of the human-soil relationship, and respond to soil-related sustainability challenges. The intricate material and scalar complexity of soils include diverse knowledge and practice systems. How communities perceive soil varies across contexts, resulting in a debate with deeply rooted social and cultural concerns. Inevitably, different assumptions and perceptions about soil influence educational practices, and what and how we teach and learn about soil. The LOESS project, a collaborative and transdisciplinary initiative, seeks to enhance soil literacy by mapping, connecting, and engaging with diverse educational levels, from primary to higher education and civil society, across 15 European countries. LOESS aims to co-create and test pedagogical techniques helping reconsider how we understand soil and foster human-soil relations, stimulating discourses between educators and learners, and bridging different knowledge systems. Wageningen University team within the LOESS project conducted qualitative research in the Netherlands educational context, exploring soil knowledge practices and the paradigms shaping human-soil relations. The research focuses on how educators envision soil education, specifically examining which paradigms-considering the mechanistic and the ecological paradigms-are chosen to enhance knowledge and cultivate a sense of care for the soil among students. The mechanistic and ecological paradigms offer different perspectives on the natural world: universal versus local, atomistic versus relational, and controllable versus chaotic. A curriculum rooted in a specific worldview shapes students' understanding of soil and environmental issues. Findings from interviews and focus groups with educators, from diverse educational levels, reveal how assumptions shape the purpose of soil education, ranging from agricultural use to environmental preservation. Educators' conceptualization of education and teaching of soil-related topics are influenced by paradigms, whether mechanistic or ecological. This study recognizes the diversity of knowledge systems and paradigms that shape human-soil relations, contributing to addressing the global soil crisis.

##### THE EMERGENCE OF TROPICAL SOILS AS A CATEGORY OF SPECIALIST RESEARCH IN BRITAIN

T. TOMKING

University of York - Leverhulme Centre for Anthropocene Biodiversity, and the Department of History, York,  
UNITED KINGDOM

In 1944, a group of British soil scientists gathered with the agricultural advisor to the Colonial Secretary at the Rothamsted Experimental Station in England to discuss the future of soil science across Britain's colonial empire. In what would be the first of many meetings, attendees outlined the need for more trained soil scientists to work in the colonies and the difficulty of establishing any uniform system of soil classification for the colonial empire with their existing knowledge. This committee, later known as the Soils Sub-Committee, would go on to influence the direction of soils research in Britain and its colonies throughout much of the post-war period. One of the features of developments in British 'colonial soil science' during this time was the emergence of tropical soils as a category of specialist research: the first conference on tropical and sub-tropical soils was held at Rothamsted in 1948, and in 1950 a Tropical Soils Adviser was also appointed for the first time. Whilst the fertility of tropical soils had been the topic of discussion in the past, this was the first time tropical soils had been given this much institutional support and attention as a specific category of specialist research, at least in Britain. The aim of this paper is to point out the broader context of British colonial development in which these events were situated. Experiences during the interwar years had a profound influence on the place of soil science in visions of colonial development after the Second World War, particularly the idea that soil surveys were an important yet difficult way of scientifically planning colonial territories. Understanding the politics of soils research in colonial contexts is helpful to unpack the meanings of tropical soils and thus some of the more contemporary controversies that have surrounded them.

##### A THEORY OF CHANGE TO UNDERSTAND THE IMPACTS OF HISTORICAL SOIL AND LAND USE APPRAISALS ON AGRICULTURAL POLICY DEVELOPMENT IN THE CARIBBEAN CONTEXT

J. PO <sup>1</sup>, M. PEREZ <sup>1</sup>, A. SAINT VILLE <sup>2</sup>

<sup>1</sup> University of Greenwich - Natural Resources Institute, CHATHAM MARITIME, KENT, UNITED KINGDOM

<sup>2</sup> The University of the West Indies - Department of Geography, ST. AUGUSTINE, TRINIDAD - TOBAGO

##### Background

Since the 1930s, British scientists carried out soil and land use surveys with the support of colonial governments. Maps, soil surveys, and aerial photos contributed to policy decisions for agriculture, forestry, and conservation. While newly independent countries have pushed to modernize agricultural systems towards national goals, critical examination is lacking on the enduring legacies of colonial structural injustice, at times, at the cost of development progress. This research critically examines how soil and land use appraisals contributed to key agricultural policies and practices pre- and post-independence in the Caribbean. The paper presents a theory of change (TOC) on decolonizing soil science via the examination of science-policy pathways in natural resource management. We ask, “to what extent did soil and land evaluations contribute to the policies and practices of colonial and post-colonial agricultural systems?”

##### Methods

We draw on literature and archival review with a focus on soil and land resource evaluations, soil-human relation within agricultural systems using archival data from Land Resources Division (formed in 1956 and part of the Natural Resources Institute since 1990) and an overview of the key actors across government and development sectors and agricultural policies of two Caribbean countries, drawing on Food and Agriculture Policy Decision Analysis policy database. The TOC is produced by an interdisciplinary team of soil scientists and social scientists via group model building (Vennix, 1996) to include critical examination of the historical contexts, methodological assumptions and limitations, societal forces under which science-policy pathways generally take place.

The study aims to examine the internationalisation of soil science under varying support towards decolonisation of agricultural science within British colonial contexts. It aims to build on existing frameworks addressing science-policy pathways in order to re-imagine more just and sustainable human-soil relations.

##### SOVIET SOIL SCIENCES IN CENTRAL ASIA: LABORATORIES FOR REMEDIATION RESEARCH

S. BAUER, T. PALLAEV

University of Oslo, Oslo, NORWAY

This contribution examines Soviet soil sciences, especially soil ecology, and its complex relations to international organizations and local research in the republics. It focuses on the work of pedologists in Central Asia and their research on soil melioration, degradation, and remediation. Since the late 1950s, Khrushchev's modernization campaigns propelled agricultural production in Uzbekistan and large-scale projects of "greening the Central Asian steppe" through irrigation and mechanization in Kazakhstan. During the 1960s, Institutes for Soil Sciences and Agrochemistry were founded in Tashkent and Almaty. Despite the strong academic tradition of the Dokuchaev school, the status of soil sciences as an academic discipline was unstable in the USSR and soil sciences were moved from the Academy of Sciences into more applied agricultural institutes. At the same time USSR soil scientists played an active role in international projects coordinated by UN agencies, dedicated to irrigation and soil salinization within UNESCO programs on desertification and, later, in the Man and Biosphere (MAB) program and the Scientific Committee of Problems of the Environment (SCOPE). Soviet soil scientists were instrumental in FAO's world soil mapping endeavor and brought Vernadskii's conceptualization of biogeochemical processes and the importance of soils in the biosphere to international attention. While a few scientists, close to the political elites in Moscow, acted as diplomats on the UN stage, local scientists in Central Asia carried out the groundwork, often under constraints and with limited access to publishing. Since the early expeditions of Russian colonial sciences, the arid steppe areas with their extreme climates as well as the cotton production regions in Central Asia have continued to function as laboratories and training spaces for soil scientists. In this paper we reconstruct these entangled pasts and describe the complex positionality of soil sciences in Central Asia in order to make visible some understudied strands of soil remediation research in the Anthropocene.

**THE COSMOPOLITICS OF SOIL RESOURCEFULNESS: THE POLITICAL HISTORY OF SOIL SCIENCES AND THE CONSTITUTION AND CONTESTATION OF AGRARIAN ORDERS**

M. MEIJER

University of Groningen, Groningen, THE NETHERLANDS

The soil humanities are committed to unearthing alternative onto-epistemologies and praxeologies of soils and soil relations which challenge hegemonic conceptions of soils as resources. Sympathetic to this program, this paper seeks to contribute to it by providing a more historically substantiated understanding of how this resource-being of soils can be theorized by outlining a cosmopolitical history of the sciences of soils.

This history is explored and organised around three scientific paradigms around soils which predominated in (European and North American) debates in a roughly chronological fashion since the 19th century: agrochemistry, agogeology, and earth system science. These paradigms have generated particular problematisations of the resource-beings of soils and have thereby been involved in the construction of technologies and practices through which soils are used and governed. Agrochemistry, with its concern with the nature and availability of soil nutrients, for instance, is linked to 19th century debates on sewage innovation and artificial fertilisers, but also to the constitution of experimental agricultural communities based on recycling principles. Similar histories concern agro-geology, pedology and more recently earth system science, whose understanding of the resourcefulness of soils contest and promote particular practices and technologies.

Rather than uniform and uncontested, then, the historical resource-being of soils involves an ongoing resourcing of soils in which soils' resourcefulness (i.e. their values and functions) and their resourcelessness (their liminalities and vulnerabilities) are redefined. Furthermore, these soil resourcings have responded to and generated concerns over widespread soil destruction since the 19th century onwards, giving rise to projects and imaginaries of (re-)fashioning human societies' values and metabolic processes through soils, primarily centered on agriculture. Through this theorisation of the resource-being of soils and an exploration of its relation to agrarian orders of different kinds, this paper seeks to raise more sharply the question of appreciating and articulating the historically situated differences and relations between alternative conceptions of soils and resource-ontologies of soils that is central to the soil humanities.

**IN THE SHADOW OF CARBON: WHAT KNOWLEDGE IS NEEDED TO REGENERATE AGRICULTURAL SOILS?**

A. KRZYWOSZYNSKA<sup>1</sup>, G. KALLIO<sup>2</sup>

#### **Affiliations**

<sup>1</sup> University of Oulu, Oulu, FINLAND

<sup>2</sup> University of Helsinki, Helsinki, FINLAND

A dramatic change — in which carbon, not just food, is becoming a key product of agricultural soils — is silently under way. Influential policy movements, such as the French-government backed “4 per 1000” initiative and the Horizon Europe mission “Soil Deal for Europe” assert that increasing the concentration of carbon in soils will significantly contribute to mitigating climate change (Vermeulen et al., 2019). Consequently, there is rapidly growing investment in the public and the private spheres into developing epistemic and technological practices which would make carbon sequestration in soils a reality on farms, and into promoting the uptake of these practices amongst farmers.

In this paper, we trouble the idea that carbon farming is an obvious ‘win-win’ for farming and for farmers. We are particularly concerned with how the carbon focus is overshadowing the more fundamental and more urgent concerns around the future of agricultural lands and of land workers. We argue that subjecting farming knowledges and practices to the objective of carbon sequestration may undermine rather than support the urgent work of rural regeneration. To regenerate rural soils and communities, we need forms of knowledge which attend to and improve relations between humans and the multiple living and non-living entities who make life possible in specific places. Focusing on carbon sequestration as the primary outcome of farming activity, and promoting carbon as the primary lens through which to understand and reconfigure farming, threatens to subject these heterogenous socio-ecological and multi-species relations to a new homogenizing knowledge paradigm. By constraining the horizon of epistemic and practical action, it also threatens to further undermine the capacity of farmers to adapt and innovate their livelihoods in durable and sustainable ways. Drawing on preliminary data from Australian farmers, we indicate the tensions between knowing soil and farming through the lens of carbon, and the holistic knowledges needed for agrarian regeneration.

**MAKING SOIL A SYSTEM: HANS JENNY'S STATE FACTOR MODEL OF SOIL FORMATION AND THE CLASSIFICATION OF CALIFORNIA SOILS**

S. TRIDENTI

Princeton University, Princeton, USA

#### **Body**

This paper delves into the development and dissemination of Hans Jenny's State Factor Model of soil formation, shedding light on its significance in the context of soil taxonomies and ecological history. Jenny's perspective offered a unique lens through which to view soil, one that positioned it as a living, dynamic entity deeply integrated into its ecosystem. However, for soil to assume this active role within ecosystems, it had to undergo a process of delineation, dissection, and abstraction. This study examines how Jenny grappled with the definition of his state factors, particularly the biotic and the human factor, as independent actors. In moments of definition and classification, Jenny resorted to establishing arbitrary boundaries, differentiating between individual soil plots as well as between soil and vegetal matter. These demarcations, combined with Jenny's systematic characterization of soil, rendered his State Factor Model particularly attractive to soil taxonomers and classifiers, especially those engaged in the United States soil survey. Much more significantly, however, Jenny's scientific interest in biotic soil characteristics dovetailed with his lifelong efforts to conserve unique soil profiles of California. This paper explores how Hans Jenny's State Factor Model of soil formation, which viewed soil as a living and integral component of ecosystems, incorporated the language of classification and boundary-making to define soil as a valuable and distinctive resource, thus demonstrating the interplay between ecological thought, soil surveying, and conservation and environmental history.

##### ACCOUNTING FOR SOIL CARE. AN INQUIRY OF SOIL ONTOLOGY THROUGH ECOLOGICAL ACCOUNTING IN AGROECOLOGICAL FARMING

C BOYER

International Center for Research on Environment and Development, AgroParisTech, Paris Saclay University, Nogent-sur-Marne, FRANCE  
DRM, Paris Dauphine University, PSL, Paris, FRANCE

In the midst of growing multidisciplinary scientific interest, heightened public awareness, and evolving political and regulatory agendas, soil is undergoing a process of mainstreaming. New practices, strategies, and tools are emerging to integrate soil ecology into organizational frameworks, particularly in spatial planning, ecological engineering, and agroecology. Despite the interdependence of most organizations with soil ecosystems, the incorporation of soil ecologization into their accounting systems and tools remains largely invisible. Accounting, serving as the architecture of organized activity, plays a central role in comprehending, modeling, controlling, and governing organizations.

This research relies on an ethnographic inquiry into the land and agroecological transitions of a former military airbase in the South of the Paris Region, France. We investigate soil preservation practices to address the emerging concern and care for soil. In resistance to urban sprawl and soil artificialization, an alternative farming collective reassigns contaminated soils, shaping novel approaches to care for and live with these soils. Consequently, they engage in soil knowledge-making practices that challenge the scientific understanding of soils, advocating for the pluralization of soil ontologies and epistemologies in agroecological transitions. We demonstrate how the design of an ecological accounting system for soil unfolds various controversies surrounding soil preservation. We introduce the concept of matters of care to define, assemble, and articulate soil food web care practices across spatial and temporal scales, thereby defining soil ontology. We illustrate how ecological accounting, extending beyond mere quantification and monetization, facilitates the expansion of care networks and constitutes a comprehensive caring project.

This paper builds upon previous research on ecological accounting by exploring the case of soil to shed light on and support collective soil management across scales. It contributes to the development of new participatory methodologies for exploring ontological controversies related to ecological transition. Lastly, this proposition offers an original perspective on soil ontology, intertwining relational ontologies and formal ontologies through accounting translation and the notion of capital.

<sup>5</sup> NATIONAL RESEARCH COUNCIL IBE, FIRENZE, ITALY

<sup>6</sup> ITALY

According to the current western narrative, to meet the food needs of a rapidly growing world population, soil must be intensively exploited leading to depletion of its nutrients and vitality, with destructive impacts on natural habitats and wildlife. This is often due to a reductionist technoscientific culture that colonizes or delegitimizes local knowledge and practices, which, over centuries, have fostered a deep, intimate, affective, and not merely instrumental relationship with the land.

At the same time, soil is also the ground where the scientific community can experiment a concrete transformation of its approaches and narratives. The experience of hybrid networks of citizens, artists, farmers around the world who carry out projects of cultural regeneration of land and food production can inspire this process. Their model is often agroecology, which questions the epistemological foundations of modern science; it is based on a non-hierarchical pluralism of knowledge and practices, with a focus on the interconnectedness of ecosystems, and on a closer relation between human and non-humans. The political awareness of the importance of taking care of soil drives these networks to save it from overbuilding and degradation, thereby reshaping the very concept of food and soil as common goods.

This presentation shares insights from the transdisciplinary project BRIDGES (Bringing Reflexivity and Response-ability Involving Different Narratives of KnowledGE and Science), which employs soil fertility as a key study to investigate the essential conditions for fostering reflectivity and hybridization in scientific research.

The project places significant emphasis on the artistic and aesthetic exploration of soil proposed as a methodology that investigates the concept of relation. Engaging with soil through the arts can stimulate critical ontological and epistemological reflections regarding the status of living beings, the relationship between visible and invisible, humans and non-humans, the boundaries and connections between different knowledge systems, the multiple narrative, and the potential for collective and multifaceted action.

##### GROUNDING CLIMATE SOLUTIONS THROUGH SOIL HEALTH: THE MICRO-BIOPOLITICS OF SOILS AS CLIMATE INFRASTRUCTURE

T. LAW

Cornell University, Ithaca, USA  
University of Oxford, Oxford, UNITED KINGDOM

In this moment of entangled climate and topsoil crisis, soil is simultaneously conceived as imperiled and as an existing climate solution. Drawing upon eight months of qualitative fieldwork in Central New York State agriculture, I trace how soil relations are shifting amidst State and farmer efforts to mitigate and adapt to climate change. Engaging recent literature on soil's relational materiality (Krzywoszynska and Marchesi, 2020), infrastructure studies (Nelson and Bigger, 2022) and political ecology (Byrant, 2018), I examine the recent attention to soils' lively components as essential climate functions, marking a shift towards envisioning and engaging soil as a form of natural climate infrastructure. I consider the biopolitical doubling of this conceptualization, how farmers are being conditioned to see soil differently via soil health extension, and how farmers enact this vision, through new attention to soil life to prepare for extreme weather and sequester carbon. I offer a typology of emerging soil ontologies and relations initiated in this visualization, including convivial, carbon and capitalist soils. I argue that through this process soil becomes both naturalized and depoliticized as a climate solution, increasingly centering a reductionistic carbon ontology of soil that precludes other soil relations. I conclude by considering how this carbon ontology amplifies capitalist relations to soil through new efforts of carbon farming, creating new avenues for value accumulation, ultimately rendering soil investable anew.

##### SOIL PERSONHOOD – ON THE POSSIBILITY OF PED-ONTOLOGICAL PROTECTION OF SOIL BEINGS AND LIVELIHOODS

A. TOLAND

Bauhaus-Universität Weimar, Weimar, GERMANY

In kinship worldviews and recent developments in environmental protection policy, recognition of personhood has been given to rivers, mountains, and rock formations. Can soils also be recognized as persons with legal standing? The concept of an individual “soil person” is hardly comparable to individual rivers, mountains or other non-human natural entities. Roy Simonson was one of the first soil scientists to note that “soils are seldom set apart from their neighbors by sharp boundaries.” Instead, soil has historically been imagined as a place where multiple spheres merge into one: the dynamic interface between biosphere, lithosphere, hydrosphere, atmosphere, and all that plays out in the technosphere. Soils at first seems to resist subjectivity because of their soft boundaries and wide-spread distribution, or what philosopher Timothy Morton calls “hyper-objects.” Human classification of individual “species” of soils—organized as soil groups such as podsols, alfisols, or luvisols— are described in taxonomic handbooks, or passed on as local knowledge.

Building on previous work, this paper expands the scope of current soil assessment procedures to include aspects of personhood such as intrinsic worth, cultural status, and the capacity for reciprocity, memory, decision-making, and social interaction. The transdisciplinary, mixed-methods project draws on ideas from the soil humanities, indigenous and feminist STS, and artistic research to recognize the subjectivity of soil beings under existential threat by multiple megatrends of the Anthropocene. Elements of instructional art, speculative fiction, and soil taxonomy are used to develop new protocols for soil personhood recognition that can be used in soil assessment. Extending Kathryn Yussof and Elizabeth Povinelli’s ideas about geontology to the soil, the paper 1) begins with examples of speculative critical design and art practices focused on engaging with soil beings and livelihoods; 2) then expands these with views from soil scientists and educators, policy experts, and soil care practitioners; to 3) argue for ped-ontological protection based on existing legal frameworks, transdisciplinary scholarship, and political resistance movements.

##### HARVESTING SOIL CARBON ON ENGLISH ARABLE FARMS

J. MAYALL

University of Sussex, Brighton, UNITED KINGDOM

A voluntary soil carbon market has recently emerged in Europe, aimed mainly at arable farmers and driven largely by FinTech start-up platforms which offer to generate and/or trade credits on behalf of farmers. Based on ethnographic research, this paper explores the process of the commodification of soil carbon within an English arable farming context. The findings suggest that much of the soil carbon being traded is unlikely to correspond to additional storage of atmospheric carbon since the farmers engaging in these schemes generally are those who have already adopted soil conservation practices, motivated by agronomic benefits and the current economic and post-Brexit policy climate. The apparently limited impact of the soil carbon trading platforms is in contrast with their portrayals of themselves as transformers of agricultural and food systems and their alignment with the regenerative agriculture movement. This is consistent with previous descriptions of 'non-disruptive disruption' within the cleantech industry (Fairbairn and Guthman, 2022; Goldstein, 2018).

**LEARNING FROM SOIL AND FARMERS: INSIGHTS FROM AN INTERDISCIPLINARY STUDY OF SMALLHOLDER FARMER USE OF HUMAN EXCRETA-DERIVED SOIL AMENDMENTS IN TAMIL NADU, INDIA**

W. BARRETT

Cornell University, School of Integrative Plant Science, Ithaca, USA

Soil scientists and agronomists can gain deeper understanding of soil and crop management practices and those practices' cultural, social, and economic implications by complementing standard soil chemical, physical, and biological assays with social science methods such as interviews and participant observations. I will discuss findings from semi-structured interviews and participant observation within my study of the use of soil amendments derived from human feces and urine among smallholder farmers in Tamil Nadu, India.

Farmers throughout the Global South have disparate access to organic soil amendments. While many national governments, including the Government of India, subsidize inorganic fertilizers, farmers typically rely on local, unsubsidized sources for organic soil amendments. Simultaneously, people in the Global South have inconsistent access to improved sanitation. Ecological sanitation (ecosan) represents an approach to ensuring that nutrients and carbon obtained from agriculture are returned to agricultural land while also providing people in both rural and urban spaces with improved sanitation.

The appearance of composted human feces, which have a lighter color and little or no objectionable odor when fully composted, was regularly identified as facilitating farmer use. Farmers also indicated that they observe benefits to rice crop health and crop yield following the application of human feces compost. These results suggest that organizations involved in the implementation of ecological sanitation should work to ensure that latrine users receive training and support in composting and agronomic advice to promote the integration of excreta-derived fertilizers into farmers' existing soil fertility management strategies.

##### BAROQUE SOIL

S. DENIZEN

Washington University in Saint Louis, Saint Louis, USA

Mexico City's ongoing environmental crisis is characterized by three primary problems: flooding, subsidence, and water scarcity. Over the course of the 20th century these problems have become increasingly inextricable from one another. Large scale urban land subsidence causes infrastructural damage and topographic changes that cause flood risk, which in turn results in ever more water scarcity and increased subsidence. Today, the consequence of this environmental condition is a silent and unacknowledged 'poverty trap' for residents who lives are subject to the precarity and perennial uncertainty of geological risk. Debts related to the repair and survival of subsidence related damage accrue disproportionately in parts of the city that are already marginalized, however the geography of this inequality is not determined by the center-periphery dynamics that historically shaped the city's urbanization. Instead, the largest debts emerge at the intersection of volcanoes and lakes, in an area whose boundaries are defined by a particular soil.

This soil, more than any other material condition, has shaped the contours and conditions of possibility for Mexico City's environmental crisis today. In this presentation, the soil's legal, technical, and metaphysical illegibility to the primary institutions of civil society in the 20th century will be considered in detail through an analysis of six key soil profiles in the Mexico City-Mezquital Valley hydrological system. Each profile takes up a different kind of illegibility through the specific soil chemistries, social relations, and historical events that have factored in the soil's formation.

<sup>3</sup> NATIONAL AUTONOMOUS UNIVERSITY OF MEXICO, MEXICO CITY, MEXICO

Soil, a fundamental resource crucial for sustaining Earth's ecosystem, often goes unnoticed due to it remains invisible and hidden beneath our feet. To address this knowledge gap, we introduce the Suelófono initiative—a pioneering podcast in Spanish dedicated to soil science. Developed collaboratively by the Proyecto Suelox and the Institute of Geology at the National Autonomous University of Mexico, with support from the International Union of Soil Sciences Stimulus Fund, Suelófono aims to provide accessible insights into various aspects of soil science.

This initiative, strategically launched during the pandemic, spans three seasons, each consisting of six episodes. The podcast features expert interviews, predominantly from Mexico, supplemented by discussions with international soil science authorities such as John Galbraith (in English), Peter Schad (Germany), and Alberto Hernandez (Cuba). Topics explored include the formation duration of soil, degradation rates, paleosols, and the presence of extraterrestrial soils.

We are delighted to report that Suelófono has been enthusiastically received in Mexico and other Latin American countries, as well as Spain, and has even piqued the interest of non-Spanish speaking nations like Turkey, Poland, and Thailand. In summary, this initiative has made a positive impact in spreading the knowledge of soil science and received international recognition when honored with the FAO's King Bhumibol World Soil Day Award 2022.

<sup>3</sup> Laboratorio de Realidad Virtual y Aumentada, UPIIH, INSTITUTO POLITECNICO NACIONAL (IPN), HIDALGO, MEXICO

Thanks to advances in augmented reality interfaces, and the use of direct-projected augmented reality (DirectAR), it is possible to display or project AR images on surfaces with arbitrary shapes or colors under random lighting environments without image distortion using a projector camera system, creating new possibilities for educative tools that would be applicable to any academic level allowing innovative and interactive learning environments. In the case of earth sciences, and specifically soil sciences, this technology has the potential to create a learning tool for bachelor students in earth and biological science areas, trying to attract students' attention through digital media in combination with real samples, seeking to develop aptitudes and analytical skills as observation for the search of detailed features of the species for identification purposes. In the present study, we use a total of 22 samples of biological soil crusts from Tehuacan Valley, Puebla México to develop a projected augmented reality system for classroom teaching, before fieldwork experience as training for the student. The present proposal aims to establish an interactive and immersive learning strategy designed for students, seeking the development of an application focused on forest and soil sciences as an alternative to what is established in the scientific literature with a medical or industrial focus, being one of the first works focused on these biological groups.

<sup>4</sup> Scuola Normale Superiore di Pisa, Pisa, ITALY

<sup>5</sup> Università di Salerno, Salerno, ITALY

<sup>6</sup> Istituto Comprensivo Statale Torquato Tasso, Salerno, ITALY

A unique museum in Italy, with few counterparts around the world, inaugurated on April 22, 2016, the day when the United Nations celebrate Earth, offering a singular knowledge journey dedicated to the soil, specifically to what happens in that space underground, fundamental for life on our planet. Beneath our feet, there is tumultuous activity, chemical, physical, and biological, upon which the landscape we inhabit, the food we eat, and our survival on the planet depend. The Soil Museum in Italy is precisely located in the Campania Region, Salerno Province, and the Municipalities of Auletta and Pertosa. The museum consists of 1,500 square meters of covered exhibition space and connected paths outside the museum. An extraordinary adventure to experience with all five senses through a series of activities to observe, touch, play, and be amazed. A narrative about soil alive and soil formation processes, and their relationships with ecosystems, living communities, and landscapes, the long-term interaction with human societies.

The Soil Museum is part of a naturalistic complex located in the Alburni Mountains, in the Cilento Geopark, which includes the caves of Pertosa-Auletta. They are also the only caves in Europe to preserve the remains of a pile-dwelling village dating back to the 2nd millennium BC, which also inspired the creation of an archaeological speleo museum a unique exhibition in the world that tells the story of the past of the caves of Pertosa-Auletta when the cavity housed a settlement on stilts and was considered a sacred place. The museum complex, managed by the MIDA Foundation, aims to be an attractive system that revolves around the enhancement of local environmental resources and cultural assets, and support for scientific and technological research. The Museum consistently promotes scientific and social research activities in synergy with local stakeholders. Its model, based on the sustainable management of environmental and cultural heritage, has been recognized as a national excellence

**RAISING THE PROFILE OF SOIL THROUGH SOIL ART**

K. KURTZ

Cornell University, Ithaca, USA

Kirsten Kurtz is an artist and soil scientist who creates paints from soil that she uses to create multi-layered paintings. She shares her methods publicly, and they are now taught in classrooms around the world.

As an artist, Kurtz led a team to win an international soil painting contest sponsored by the United Nations-Food and Agriculture Organization to celebrate World Soil Day 2017, and she has been recognized as an Artist for the Earth by the Earth Day Network. As a scientist she manages the Cornell Soil Health Laboratory, a leader in soil health assessments. In both roles, she endeavors to draw global public attention to soil as a precious natural resource, as important to our quality of life as clean air and water.

Kurtz will share a digital art show of her work as she discusses the historical use of soil pigments in paint and her work communicating the importance of soil through her commissioned pieces, soil painting events and the media coverage of her work. She will offer practical tips on holding soil painting events for the public, share her methods for inspiring interest in soil and discuss the power of creative scientific communication.

**DEATH TO THE BORING BROWN BLOB!**

K. VANCAMPENHOUT

KU Leuven, Leuven, BELGIUM

'It is a shame that the many excellent and interesting papers by soil scientists remain confined to library shelves. New findings by chemists, geologists and ecologists are regularly reported by the media, but new information about soils is overlooked.' - These are the words of Hans Jenny, written in 1984. Forty years later, despite the shift from library shelves to digital databases, soil science still struggles for recognition in popular science communication. In the face of global challenges tied to soil, it is imperative for soil scientists to enhance their efficiency in popularizing their discipline. Unfortunately, efforts thus far have often resorted to portraying soils as a 'boring brown blob,' a misleading oversimplification hindering public engagement.

Beyond being inaccurate, oversimplification lacks intrigue and fails to convey the soil as a living, integral part of ecosystems susceptible to degradation. Protecting a generic brown substance is hardly a compelling message. Moreover, it denies non-specialists the opportunity to explore soils themselves. Pedology plays a crucial role in providing the language needed appreciate the below-ground world. Just as amateur ornithologists or astronomers start by learning names of birds and constellations, understanding the natural beauty, variability, and occurrence of soils begins with basic soil types as a foundational language for comprehension.

Basic pedology is not overly challenging—remembering 32 soil reference groups or 12 soil orders is comparably straightforward. The challenge lies in how the information is presented. Soil heritage, in-situ or in exhibits, provides an excellent starting point to introduce soil stories and language. As the below-ground world remains hidden from most, uncovering the beauty and legacies of soil heritage sites can create the immersive, authentic experiences needed to reconnect people to soils.

Drawing on numerous personal experiences in soil storytelling, exhibits and installations, this contribution explores effective methods to communicate soil science, emphasizing the need for engaging narratives that captivate audiences and facilitate a deeper engagement with the intricate world beneath our feet.

#### TALES OF THE SOIL: BRIDGING THE GAP BETWEEN SOILS AND PEOPLE

S. MANTEL

ISRIC World Soil Information, WAGENINGEN, THE NETHERLANDS

Soil is a complex and variable medium. Even though soils are omnipresent and essential for life, most people are unfamiliar with the resource. The complexity and hidden nature of soil is only partly the cause for lack of awareness of soil as a resource and its functions. The general lack of perception of soils means that sensory information on soils is not processed to the extent that it leads to understanding and awareness. In other words, people that have no education or prior knowledge in soils need to be introduced to it to be able to engage in it and appreciate it.

The World Soil Museum informs and educates about the nature and the diversity of soils and what that means for society and for science. The museum displays soil monoliths from around the globe. Soil monoliths are undisturbed, vertical soil samples of about 1.5 m depth. They present the soil very close as to how they are seen in a profile pit in the field, with the layering, colors and structure of the soil. The monoliths are accompanied by physical and digital media. The gap between the visitors and the topic of soils and the monolith collection is bridged through guidance and tours and is supported with digital (online) media and audio-visual material. Storytelling is used to bring soils closer to people in a way that it inspires and is more easily remembered so that it will be passed on in communication between people. Stimulating stories are told of soils placed in the context of society. They stick to the mind as they link with perception and understanding of the public on topics such as people, history, land management, food security, and climate change. Examples are given of these stories and how that stimulates learning and dialogue with museum visitors.

**THE LEGACY OF URBAN SOILS IN BRUSSELS (BELGIUM)**

Y. DEVOS<sup>1</sup>, L. VRYDAGHS<sup>1</sup>, A. DEGRAEVE<sup>2</sup>

<sup>1</sup> Vrije Universiteit Brussel, Archaeology, Environmental Changes & Geo-Chemical Research Group (AMGC), Brussels, BELGIUM

<sup>2</sup> Urban.Brussels, Brussels, BELGIUM

Urban soils have been largely neglected for a very long time. Illustrative for this is for instance the Belgian soil map that shows a blank for the urban areas. Over the last decades there is an increased interest in the urban soils. One of the triggers are the manifold archaeological excavations realized in urban areas. Facing the complexity of the urban stratigraphy, archaeologists started to involve geoarchaeologists in their research. In Brussels this led to the systematic study of urban soils on all the archaeological interventions, whatever their size (Devos et al., 2020). Whereas initially the main research topics concerned the understanding of complex site stratigraphy, the last decades the perspectives widened and new avenues, such as the understanding of late medieval agricultural and horticultural practices in an emerging city, the organization of urban space, the preservation of urban soils and ancient soil pollution, were explored. It also resulted in the development of an interdisciplinary research protocol to tackle the emerging research questions.

The present contribution intends to illustrate how the improved understanding of the formation of urban soils in Brussels impacts on the current research, and how it creates awareness for the importance of urban soils for past, current and future communities.

Urban soils are receiving increasing attention due to the large number of ecosystem services these provide: a resource for local food production, fostering social community resilience, and serving as a means to enhance green spaces within urban areas. However, their quality is largely impacted by anthropogenic activities including industrial operations and traffic emissions. As a result, they act as both primary and secondary potential-pathways for the exposure of humans and the ecosystem to potentially toxic elements. While extensive research has focused on heavy metals in soils, a thorough assessment of potential risks to urban dwellers requires studying a wider range of elements, especially those found in ultra-trace levels with poorly understood ecotoxicological effects from chronic exposure to low doses. To address these knowledge gaps, we surveyed topsoils from 20 urban allotments and 17 parks across Barcelona (Spain) and determined the concentrations of 55+ elements, as well as their 0.01M KNO<sub>3</sub>, 0.05M EDTA and 0.005M DTPA extractable concentrations as estimates of their bioavailability. We also size-segregated soils to extract the involuntarily ingestible and inhalable particles to examine multi-pathway exposure estimates. The majority of soils were relatively unpolluted, with only few sites showing high metals loading reflecting anthropogenic inputs. In general, the mobility of elements was moderately low although the EDTA and DTPA-extractable pools of several specific trace elements deemed worth further investigation. Our findings also evidence that the physiologically relevant soil particles (i.e <250µm) are compositionally different to the bulk soil in terms of levels of total and mobile trace/ultra-trace elements. Two in-vitro tests simulated dissolution processes in lung environments following inhalation, while another mimicked gastrointestinal dissolution. Results revealed that only a limited number of trace elements are soluble in the (sub)ppm range in these synthetic fluids. Our findings suggest that while total concentrations are the exposure metrics used by guidelines, other estimates may provide more accurate environmental assessments of the fine surface particulates and their potential impact on human health.

#### COMPARATIVE ANALYSIS OF GREEN ROOF SUBSTRATES WITH RECYCLED MATERIALS: A THREE-YEAR STUDY

M. PETREJE <sup>1</sup>, B. RYBOVA <sup>2</sup>, P. HECKOVA <sup>1</sup>, M. SNEHOTA <sup>1</sup>

<sup>1</sup> Czech Technical University in Prague - Faculty of Civil Engineering, Prague, Czech Republic, Prague, CZECH REPUBLIC

<sup>2</sup> Czech Technical University in Prague, University Centre for Energy Efficient Buildings, Bustehrad, Czech Republic, Bustehrad, CZECH REPUBLIC

The study aimed to test newly developed green roof substrates containing a significant amount of recycled materials under real conditions and compare them with a commercially available substrate.

A two-layer extensive green roof of 7×5 m<sup>2</sup> was constructed using three different substrates. Two of them were based of recycled materials to reduce primary materials extraction and increase the utilization of recycle. These two substrates contained the same amount of recycled demolition waste with major proportion of crushed brick (37.5% by volume), but differed in the amount of pyrolyzed sewage sludge biochar (9.5% by volume in one and none in the other). The commercial substrate consisted mainly of expanded shale, lava and pumice. To enhance the water retention layer, hydrophilic mineral wool was used as the bottom layer of the green roof system. Vegetation was established using sedum carpets.

The experiment was established in 2020. Undisturbed substrate samples were taken in 2021, 2022, and 2023 to monitor changes in hydrophysical properties, such as retention curves, saturated hydraulic conductivity, and grain size. Vegetation development was visually monitored over time, while substrate temperature and humidity were continuously measured by autonomous sensors.

The results showed that plants in the biochar amended substrate rooted faster and achieved higher cover. Plants in the biochar-containing plot remained lush green for a longer period, even during periods of lower rainfall or more extreme temperatures, while those in plot with commercial substrate or without biochar turned red in response to stress. Moreover, the biochar-amended substrate showed a greater number of emergent plants, primarily grasses which is attributed to the increased availability of nutrients from biochar.

The surface temperature amplitudes were higher than those of the substrate and mineral wool temperatures, locally influenced by the plant biomass surrounding the sensors. The temperatures of the substrate and hydrophilic mineral wool were more stable. Differences in substrate temperatures were observed particularly between substrates containing recycled materials and the commercial substrate.

**Keywords:** Recycled material, Green roof substrate, Biochar, Recycled demolition waste

**EFFECT OF PLANT SUCCESSION ON PROPERTIES OF TECHNOSOLS DEVELOPED ON A HEAP OF HISTORICAL POLYMETALLIC ORE MINE IN RADZIMOWICE, SUDETY MTS., SW POLAND**

D. MURACH<sup>1</sup>, L. UZAROWICZ<sup>1</sup>, W. KWASOWSKI<sup>1</sup>, A. PEDZIWIATR<sup>1</sup>, K. NIZINSKA<sup>1</sup>, P. NAWROCKA<sup>1</sup>

<sup>1</sup> Warsaw University of Life Sciences - SGGW, Institute of Agriculture, Department of Soil Science, Warsaw, POLAND

Metal ore mining results in the formation of mine waste heaps, which formerly were not reclaimed and were subject to spontaneous plant succession, which initiated the formation of Technosols. The aim of the study was to determine the influence of plant succession on soil properties of Technosols developed on a heap of historical polymetallic ore mine. The study area was located in Radzimowice, Sudety Mountains, SW Poland, where copper and silver ores were mined (from the 15th century to 1925). A sequence of three soil profiles on a heap representing areas with increasing degree of natural plant succession (profiles RA1<RA2<RA3), was studied. Standard soil science research methodology was applied to determine soil properties. X-ray diffraction method was applied to determine soil mineral composition. Total content of trace elements was measured, as well as mobile forms of these elements dissolvable in H<sub>2</sub>O and 0.1M HCl were determined. The investigated soils were strongly skeletal with fine earth characterized by loamy texture. The pH value of the soils ranged from 4.4 to 7.8. The total organic carbon (TOC) content ranged from 0.29% (C horizons) to 43.8% (O horizons). The Ca<sup>2+</sup> dominated among the basic exchangeable cations in the sorption complex. Quartz and mica were predominating minerals, followed by chlorite, feldspars and admixtures of calcite. According to Polish regulations, the studied soils were contaminated with As, Cu and Pb. The permissible contents of Co and Sb were exceeded in some horizons. The trace elements studied are stable in H<sub>2</sub>O. In 0.1M HCl, Cu, Cd and Co had high mobility (above 20% on average), whereas Mn, Ni and Zn were slightly mobile. Arsenic, Cr, Sb and Fe were the least mobile elements. Research showed that the appearance of vegetation on the mine waste heap caused the accumulation of soil organic matter (SOM) in the topsoil. The accumulation of SOM caused soil acidification and increased the cation exchange capacity in the upper parts of the profiles.

Soil sealing is a prominent feature of urbanization. Yet it leads to numerous pressures: destruction of natural habitats, increase of floods, urban heat island effect. Current climate and biodiversity crisis led to question this type of land management with desealing of urban soils. Moreover, while sealing effects on soil are well-known, desealing effects are less characterized. Using a holistic approach to characterize the evolutions of urban soil after desealing is thus crucial to understand the effect of such practice on water, soil and biodiversity, but also the underlying mechanisms and the required time to retrieve a functional soil.

Permeasol aims at studying the ecological trajectory of a desealed urban soil over 3 years: can this intervention allow the growth of a functional ecosystem, to what extent and how fast? This project questions the long-term effects of urban soil sealing, even after desealing.

Three plots were desealed – removing the asphalt layer –, between September 2023 and January 2024: two located in an urban environment (Strasbourg, France) and one in a nearby forest. Sealed surfaces directly next to each desealed plot (~600m<sup>2</sup> each) were maintained: the evolution of this control allows comparing the dynamics of desealed and sealed soils.

Several analyses are regularly carried out to try and integratively capture the system dynamics: water infiltration and storage, quantity and functional characteristics of vegetation and soil microorganisms, soil fertility and pollution, and soil chemical composition. The interactions and loops between associated processes will be investigated.

At first, the desealed soils were characterized as a sand/gravel mix (~70% of soil particles >2mm) with little organic matter (~1%), low biological activity (~220mgC/kg) and no plants. Water infiltration has significantly increased after desealing. Vegetation appeared within a month, with both pioneer and typical asphalt-specific species. Soil heat decreased following desealing, and is expected to maintain this pattern with vegetation growth. Both water storage and organic matter content are expected to increase in the next months.

**INNOVATIVE APPROACH ENABLING SOIL AND FOOD QUALITY IN VEGETABLE GARDENS OF THE METROPOLITAN AREA OF NAPLES**

A.G. CAPORALE<sup>1</sup>, N. SUCIU<sup>2</sup>, P. ADAMO<sup>1</sup>

<sup>1</sup> Department of Agricultural Sciences, University of Naples Federico II, Via Università 100,, Portici, ITALY

<sup>2</sup> Department for Sustainable Food Process, Università Cattolica del Sacro Cuore, Via Emilia Parmense 84,, Piacenza, ITALY

Urban soil is a non-renewable resource, threatened by anthropic activities, infrastructure sprawl and sealing. Urban agriculture is a common practice enabling a sustainable use of soil and enhancing its ecosystem services. Although many soils in the metropolitan area of Naples are already used for crop production, little is known about soil health and food quality/safety.

The research activities of 2-year HealthySoil4QualityFood project (CUP-E53D23011040006 PRIN-2022, financed in the frame of European Union Next Generation EU), aim at increasing the knowledge on: i) soil fertility and possible chemical contamination in vegetable gardens of Naples metropolitan area; ii) irrigation water quality; iii) crop biodiversity and sustainability of cultivation practices, and chemical quality of edible biomasses (mineral nutrients, bioactive compounds and possible contaminants); iv) risks associated to possible contamination, throughout integrated environmental and human exposure modelling; v) public awareness about soil ecosystem services and social benefits of urban farming.

Five case studies were recently selected based on geographical distribution and proximity to potential sources of contamination, scope of cultivation (self-consumption of crops or educational gardens) and type of land users/farmers. In these areas, we started assessing the soil physicochemical properties and fertility and irrigation water quality. The first results evidenced an overall good quality of urban soils, showing a sandy-loam texture, neutral-to-sub-alkaline pHs, good nutrient bioavailability and low-to-moderate occurrence/bioavailability of contaminants. The nutritional value and safety of food products will be monitoring in different growing seasons. Realistic exposure scenarios to possible contaminants in each case study will be developed by MERLIN-Expo tool.

The cultivation techniques and the management of vegetable gardens will be oriented toward sustainable/resilient and site-specific models, leading to a better use of resources and enhancement of soil fertility, biodiversity and food quality/safety. At the end of project (Oct 2025), HealthySoil4QualityFood will integrate the obtained information and, in collaboration with main stakeholders engaged during the project, will develop specific indicators and guidelines to better assess and manage the soils in urban environments.

### TRANSPLANTATION OF GIANT TREES USING PEAT-BASED GROWING SUBSTRATE

K J KIM<sup>1</sup>, D S LEE<sup>2</sup>

<sup>1</sup> The University of Seoul, SEOUL, SOUTH KOREA

<sup>2</sup> Daeji Development Co., Ltd., SEOUL, SOUTH KOREA

There are many giant trees (old trees, protected trees, natural monuments, etc.) in cities and provinces in Korea. These giant trees are threatened with survival due to various factors such as changes in the ecosystem caused by urbanization and industrialization, land use change, environmental pollution, and submersion caused by dam construction. As a result, the need for transplantation of many giant tree has emerged in Korea since the early 1980s. In this paper, we would like to share experiences of giant tree transplantation using growing substrate developed from peat resources in Korea. Two most famous cases are 400-year-old Chinese scholar tree (*Styphnolobium japonicum* L. Schott) transplanted at the Central Agricultural Cooperatives in Seoul in 1983 and 780-year-old ginkgo tree (*Ginkgo biloba*) transplanted in Yonggye-ri, Andong in 1993. Due to construction of a new building, the Chinese scholar tree was transplanted some 100 m from the original location. Submersion of Yonggye-ri, Andong caused by a dam construction was the reason for transplantation of the important giant tree. It took 6 months to transplant (lift) the ginkgo tree 17.5 m from the original position. The space between the original position and transplanted position was filled with the peat-based growing substrate. The growing substrate used in this study had superior water and nutrient holding capacity compared to coir-dust- and moss-peat-, the widely used components based growing substrates. In addition, the growing substrate for this study can be mixed with other materials such as all kinds of chemical fertilizers, growing substrates, compost, perlite, vermiculite, zeolite, etc. Therefore, the potential use of the growing substrate used in this study can be expected to indoor plants and agricultural purposes.

**MICROBIAL COMMUNITIES OF URBAN AND INDUSTRIAL POLLUTED SOILS IN THE RUSSIAN ARCTIC**

M. KORNEYKOVA<sup>1</sup>, S. VASENEV<sup>2</sup>, E. KOZLOVA<sup>1</sup>, A. SOSHINA<sup>3</sup>, A. DOLGIKH<sup>4</sup>

<sup>1</sup> RUDN University, Moscow, RUSSIA

<sup>2</sup> Wageningen University, Wageningen, THE NETHERLANDS

<sup>3</sup> Institute of North Industrial Ecology Problems of KSC RAS, Apatity, RUSSIA

<sup>4</sup> Institute of Geography, Russian Academy of Sciences, Moscow, RUSSIA

Russian Arctic is a unique research area where soil is affected by high anthropogenic pressure coinciding with severe climatic conditions. The effects of urbanization and industry on SMC in the Russian Arctic remain overlooked. This research aimed to compare urban (Murmansk, Apatity) and industrial polluted (Pechenganickel copper nickel plant, Kandalaksha aluminum plant) soils to natural Podzols and explore relationships between chemical pollution and microbial properties. The SMC activity and diversity were analyzed based on 1) number of rRNA microbial gene copies by real-time PCR method; 2) community level physiological profile of SMC by MicroResp<sup>TM</sup> technique; and 3) taxonomic diversity of SMC by metabarcoding. The principal changes in urban soils' properties compared to the natural references included a shift in pH and an increase in C and nutrients' contents. Industrially polluted soils had a higher content of heavy metals (copper-nickel plant), fluorine and aluminum (aluminum plant) compared to urban and natural soils, whereas carbon content and pH were similar to natural references. The SMC structure in all soils was dominated by bacteria, however the share of fungi in urban soils was four and times higher compared to soils of natural and industrial areas. Industrial pollution decreased microbial biomass and diversity, whereas an opposite pattern was found for urban soils, where the number of rRNA gene copies and Shannon diversity index were significantly higher than in natural Podzols. The taxonomic structure of fungal communities was sensitive to the type of anthropogenic influence with the specific species dominating SMC in urban (e.g., Sordariomycetes) and industrial (e.g., Agaricomycetes) areas. Urban and industrial development represent the two alternative pathways of SMC evolution in anthropogenically disturbed soils. Industrial development suppresses SMC, whereas urbanization including development of urban green infrastructures creates a new niche for SMC. These outcomes highlight the potential of urban soils to support microbial diversity and functionality that shall be considered for sustainable development strategies and soil-based solutions in vulnerable ecosystems of Arctic cities.

##### EFFECTS OF RAINWATER HARVESTING PITS ON SOIL MOISTURE IN CZECH TEMPERATE FORESTS

T. VICHTA<sup>1</sup>, A. KUCERA<sup>1</sup>, V. VRANOVA<sup>1</sup>, K. ZLATUSKA<sup>2</sup>

<sup>1</sup> Mendel University in Brno, Department of Geology and Soil Science, Brno, CZECH REPUBLIC

<sup>2</sup> Czech University of Life Sciences Prague, Department of Forestry Technologies and Construction, Prague, CZECH REPUBLIC

In temperate climates, efficient use of rainwater is becoming an increasingly important tool for maintaining soil moisture in sustainably managed forests. Here, we describe the use of rainwater harvesting pits to concentrate rainwater infiltration into deeper layers to maintain soil moisture at suitable levels in beech (*Fagus sylvatica*) forests. In spring 2022, two 6.5 m<sup>3</sup> test pits were established alongside forest roads at two test localities, the first a “dry” locality, characterised by low soil moisture, spatial homogeneity and Cambisols, and the second a “wet” locality, characterised by increased heterogeneity, with hydromorphic Stagnosols and Gleysols dominating. In each case, one pit was located near a pipe culvert and the second at a site with no centralised inflow. In addition, soil moisture was assessed in the same stand, away from the test pits, as a control. Soil moisture was monitored at depths of 10, 30 and 60 cm, 1 m from the pit edge, on the left, right and downslope sides. Here, we present preliminary results (7/2022 – 12/2023) showing the soil hydrological response to pit installation at the two localities. Early results indicate that i) the pits show unexpectedly low efficiency in retaining rainwater in the soil; ii) in winter, soil moisture around the pits increased to soil-water retention capacity more rapidly than at the control site; iii) despite this, soil drying was similar between pits and the control site over the 2023 growing season; and iv) both test pits showed less soil moisture variability during rainfall events than the control site, most likely due to a reduction in preferential pathways in soil around the pits. Despite the range of natural hydric conditions tested at the localities (wet/dry), the rainwater harvesting pits appear not to have fulfilled their expected potential for supporting the soil hydric regime. Nevertheless, soil moisture monitoring will continue at both localities to assess any long-term effects on soil hydrology.

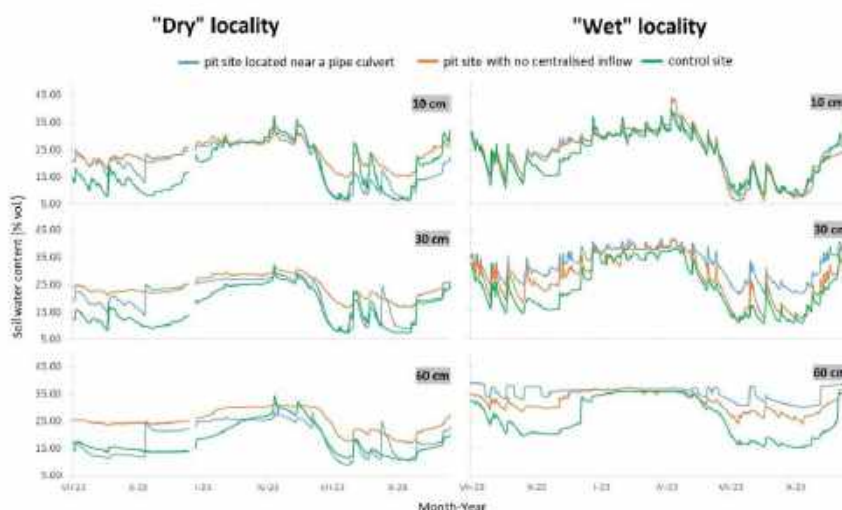

Fig. 1 The course of daily mean soil moisture at the monitoring sites of both localities (“dry”/“wet”), measured at different depths

##### OPPORTUNITIES FOR VARIABLE RATE IRRIGATION IN RESPONSE TO VARIABLE SOILS

T. PETERS

Washington State University, Pullman, USA

Variable rate irrigation (VRI) is the ability of an irrigation system to apply different amounts of water to different areas of a field. This is usually done because of differences in soil water-holding capacity throughout the field. Irrigation technology has advanced to where this capability is possible, especially with center pivots, the most popular irrigation system in the United States. VRI is done by either varying the speed of the irrigation system or by cycling sprinklers to apply different amounts of water along the pivot lateral, or both. This publication will take a theoretical approach to estimate the amount of water and power savings that can be achieved through variable rate irrigation technologies. Modeled water and power savings are estimated for a variety of different conditions. We will also discuss the conditions under which large water and monetary savings are most likely to be realized.

##### DRAINAGE- FROM SECURING PRODUCTIVITY- TO ENVIRONMENTAL PROTECTION IN NORWAY

L ØYGARDEN, Å KVIFTE, S KVÆRNØ, M BECHMANN, J STOLTE, J DEELSTRA

NIBIO, ÅS, NORWAY

Northern conditions have high seasonal variations -wet climate and winter period with frozen soils and snow cover. Short growing season and wet soil restrict possibilities for agricultural production. In Norway, the National Soil Inventory has classified that about 2 /3 of the agricultural area need drainage for agricultural production. In the middle of the 1800 silty soils were cold in spring and had low nutrient status and was valued low. Before 1860 the drainage methods were open ditches, narrow channels with stones. Tile drainage started from about 1860 and increased from about 1920. There was a main change in drainage activity and systematic drainage between 1950- 1970 resulting in yield increase between 20- 30 %. More use of tractors and machinery lead to increased need of drainage. Subsidies for drainage – covering up to 40 % of costs also promoted the activity. New mechanisation for drainage and specialised contractors also boosted the activity. Plastic pipes were introduced by the end of the sixties. Subsidies for drainage was ended by the end of the 1980-ties and led to very low drainage activity-even though economic analyses showed it was economic profitable. Now, large area need new drainage on parts of the area or on entire fields. Heavier machinery have led to soil compaction, reduced yield and increased runoff, erosion and loss of nutrients. In Norway, this has led to new introduction of subsidies for drainage on earlier drained areas. Changes in climate with more wet and rainfall period needs new recommendations of drainage design and intensity. Now there is also documented that nitrogen is being lost through drainage system and that measures like controlled drainage, or wetland to reduce losses. Drainage can also transport both erosion particles and phosphorus to waterbodies through cracks and preferential flow. Drainage plays also a role in controlling emissions on greenhouse gases. Drainage needs to be balanced both for agriculture and for environmental purposes.

##### ESTIMATION OF TRAVEL TIMES TO GROUNDWATER IN ALLUVIAL SOILS

M S M ABDELMAQSOU <sup>1</sup>, S B M HASSAN <sup>2</sup>, A VACCA <sup>1</sup>, A COPPOLA <sup>1</sup>

<sup>1</sup> Department of Chemical and Geological Sciences, University of Cagliari, Monserrato (CA), ITALY

<sup>2</sup> School of Agricultural, Forestry, Food and Environmental Sciences, University of Basilicata, Potenza, ITALY

Soil properties determine the probability of percolation and diffusion of contaminants from the ground surface into the groundwater system. Predictive tools are now available for understanding and predicting nonpoint-source pollution coming from agrochemicals use in terms of impact on soils, as well as on surface and subsurface water. Different modelling solutions exist, mainly differing on the role of the vadose zone and its horizontal and vertical variability in the predictive models. In our study, we used the FLOWS 1D physically-based agrohydrological model, which allows to explore the interactions among hydrogeological factors, such as soil properties, groundwater depth, and climate conditions. By simulating water flow and solute transport in the unsaturated zone using the Richard Equation and the advection-dispersion equation, the study integrated a dataset encompassing soil horizons, average annual soil profile depth to the groundwater table (ranging from 1 to 44.58 meters), soil hydraulic properties of 36 soil profiles, and climatic temporal series data on rainfall and evapotranspiration in a coastal plain in south-east Sardinia (Italy) with soils formed on different alluvial sediments. Detailed descriptions of travel times for the transport of 25%, 50%, 75%, and 100% of the solute mass through the soil profile to reach groundwater were calculated. Results showed large differences in the magnitude of the different travel times among different profiles. This is because alluvial soils exhibit highly intricate textural layering, with significant variation in thickness between horizons. Unlike other soils, the impact of textural layering on water flow and solute transport in alluvial soils may be quite critical due to sometimes abrupt transitions between different textural layers within the soil profile. The relatively lower or higher travel times were found to be mainly related to the depth to groundwater. However, this relationship weakens with increasing groundwater depth and solute mass to be recovered, indicating an increasing role of the soil variability for larger travel times.

<sup>2</sup> The University of Sydney, Sydney, AUSTRALIA

<sup>3</sup> Zhejiang University, Hangzhou, CHINA

Reactive nitrogen (Nr: all species of N except N<sub>2</sub>) is essential for agricultural production and human nutrition, but its use is also one of the largest causes of global pollution with serious impacts on human health, biodiversity and ecosystem services, and costs for society. Nr pollution induced by agri-food systems is the global aggregate of millions of diverse producers/products, operating/ produced under vastly different climates, soils and agronomic management, and further complicated by the international trade and socio-economic impacts. To identify effective solutions for this diverse agri-food systems, we present a framework to quantify evidence-based nitrogen (N) indexes to characterize the Nr performance with different Nr loss pathways (losses as N<sub>2</sub>O, NO<sub>x</sub> & NH<sub>3</sub>, aqueous NO<sub>3</sub><sup>-</sup> and with food losses/waste) at varying levels of detail and complexity. This framework allows comprehensive assessment of Nr loss, Nr loss intensity - Nr loss per unit of food or per unit of N produced (NLI) - for individual food items, which are indicators of associated environmental impacts and societal costs. We demonstrate how our N indexes can be used to, firstly, establish N labelling and rating to incentivize farmers to adopt more sustainable N management practices and to guide consumer choice for food products with lower NLI; secondly, identify hotspots of Nr loss and estimate the associated environmental impacts and societal cost of N pollution; thirdly, estimate Nr loss responsibility driven by consumption to allocate a fair share of responsibility for reducing global Nr loss; fourthly, highlight regions, agri-food systems, and management practices as potential foci for mitigation; and ultimately, make global agri-food systems more sustainable, less polluting and more profitable.

Carbon and nitrogen are pivotal elements in the global biogeochemical cycle, exerting significant influence on air and water quality, biodiversity, and human health. Over the past four decades, China has released substantial amounts of carbon and nitrogen compounds into the environment, resulting in noteworthy global and regional repercussions. To effectively monitor and regulate these chemicals, we have developed an integrated model (CHANS-CN) for quantifying carbon and nitrogen budgets in China, investigating their interplay on an ecosystem scale from 1980 to 2020. During the study period, carbon emissions experienced a 6.9-fold increase, while nitrogen emissions saw a 1.3-fold rise, shifting from predominantly agricultural emissions before 2000 to industrial emissions thereafter. Strategic management of carbon and nitrogen in tandem holds the potential for a 75% reduction in nitrogen pollutants released into the air and water, coupled with a 91% decrease in carbon emissions to the atmosphere by 2060. In comparison to the separate control of carbon or nitrogen, co-management could result in an additional reduction of 1.8 million tons of nitrogen and 26.6 million tons of carbon by 2060 for China. This approach comes with a 42% decrease in unit abatement costs and an overall societal benefit of 2,298 billion USD. These findings underscore the necessity of joint carbon and nitrogen management, aligning with China's overarching goals of achieving zero carbon emissions and fostering clean air and water initiatives synergistically.

##### MODELING SOIL CARBON CHANGES IN CLIMATE-SMART PRACTICES WITH A MULTI-MODEL ENSEMBLE APPROACH IN THE US MIDWEST

B. BASSO, T. TADIELLO, A. FOWLER, F. MAUREIRA, L. PRICE, P. SHARMA, S. ALBARENQUE, B. BAER, C. VILLALOBOS

Michigan State University, East Lansing, USA

This study explores the potential of a multi-model ensemble approach to assess the impact of climate-smart practices on soil organic carbon in agricultural soils across the US Midwest.

We employed eight distinct cropping system models, encompassing a time span of 30 years and a resolution of 4x4 km<sup>2</sup>, across 12 States in the US Midwest. We implemented different climate-smart scenarios based on variations in tillage practices (no-till and conventional till) and nitrogen management (full required N application and 75% of it). The multi-model ensemble approach demonstrated promising results in capturing the differences between climate-smart practices. The accuracy of the ensemble's overall mean varied depending on the time span and soil depth under consideration.

By using multiple models, we were able to reduce uncertainties and constraints inherent in individual models, thereby enhancing the accuracy of our assessments. This novel approach holds promise for advancing climate-smart agriculture and could pave the way for more informed decision-making in the face of climate change challenges.

<sup>4</sup> The University of Sydney, Sydney, AUSTRALIA

Integration between sustainable agricultural practices, environmental considerations, and economic viability is crucial for the long-term health of the agricultural sector. Here, we conduct a comprehensive analysis of the direct nitrogen (N) flows in cropland and the embodied losses in intercounty trade related to agriculture across 1690 counties in China in 2015 using multiregional input-output analysis. Results show that the total direct Nr losses in cropland was 54.5 Tg N yr<sup>-1</sup>, while the embodied Nr losses was 30.1 Tg N yr<sup>-1</sup>. Counties in the East exhibited the most significant embodied N net inflow, and counties in the northeast had the largest embodied N net outflow. Better N management could lead to a 49% reduction (10.4 Tg N) in synthetic N fertilizer inputs, with a 35% decrease (19.1 Tg N) in direct Nr losses and a 41% reduction (12.3 Tg N) in embodied Nr losses while meeting the food demand in 2050. The reduction of synthetic N fertilizer use could achieve 29.1 billion \$ economic benefits due to cost saving for farmers and ecological gains, simultaneously causing the varied impact on economic sector, such as yield price and labor demand. Setting the intercounty cooperation mechanisms and allocating a fair share of responsibility for reducing Nr loss can help improve agricultural sustainability.

**Keywords:** sustainable N management, embodied emissions, intercounty trade, reduction obligations

In the next future, the carbon footprint per unit of surface area will define the farmers capability selling their products on the market. Agricultural products with a lower impact on the carbon footprint will have a higher value, potentially leading to a higher income for the farmer. In this context, the definition of a carbon intensity score, as a metric of the environmental impact of different agricultural practices application, will support the future UE community programs providing the correct carbon credit to each single field. Therefore, the scientific community together with the farmers need to start planning the way to accomplish these new programs. In the complex system of the carbon footprint estimation, our study tries to combine the classic Life Cycle Assessment approach with the state of the art of the carbon sequestration modeling in agricultural soils. Our approach aims to define quantify the carbon intensity of maize grown in Po' Valley by accounting for the carbon emissions and the soil carbon sequestration at the same time, providing an accurate carbon footprint when applying different regenerative agriculture practices (RA). The case of study is the Emilia Romagna region, where different regenerative agriculture practices (with different tillage intensities and crop rotations) were applied over large scale to evaluate the emissions and soil's potential as carbon sink. The results offer a better understanding of the impact of different RA and provide the scientific base for a better understanding on the possibility that farmers, industry and society have to mitigate and adapt to climate change.

The ongoing transition towards global decarbonization to achieve sustainable development goals of Agenda 2030 entails a shift in land use, particularly for accommodating to the implementation of renewable energy sources such as solar energy. Nevertheless, the expansion of photovoltaic farms (PVF), which require extensive land areas situated in arid or semi-arid zones, contributes to the degradation of these already impacted regions. It exposes soil to substantial alterations that involve depletion of key soil functions, thereby adversely affecting biodiversity and ultimately their capacity to provide ecosystem services.

Traditional restoration practices often result unfeasible due to the inherent climatic characteristics in these drylands and the especially adverse environment following soil degradation during construction of PVF. However, the utilization of native biocrusts coupled with the installation of solar panels (PVP) which provide partial shading, less extreme temperatures and reduced evapotranspiration offers a promising alternative as biocrust nursery.

Within this framework we propose employing native biocrust forming cyanobacteria to reinstate soil functions after installation of PVP to prevent erosion, conserve soil microbiome biodiversity, and promote ecological restoration and succession. We investigated the effect of soil inoculation with a consortium of cyanobacteria alone or combined with different mulching treatments based on by-products derived from native plants, in soils with contrasting particle size distribution within a PVF in Almeria, SE Spain. We found that the inoculum application especially combined with plant-based mulches have a positive effect on the survival and growth of cyanobacteria and on soil properties, as evidenced by an increase in chlorophyll content and gain in soil organic carbon, with differences between soil textures. We can conclude that the application of this inoculum facilitates the development of an incipient biocrust under PVP conditions in both textures contributing to restoring soil functions. This represents a novel and highly interesting strategy for addressing the need for ecological restoration and integrating it with sustainable development in PVF.

##### SYNERGIES IN COLLABORATIVE MULTI-SCALE SOIL ORGANIC CARBON MODELLING

J. PADARIAN

The University of Sydney, Sydney, AUSTRALIA

Soil organic carbon (SOC) is a crucial component of terrestrial ecosystems. In agricultural systems, it is considered the key indicator of soil health but, given the current pressure to increase food production, soil resources are under threat all over the world. It is critical to monitor changes in soil across the planet, not only to identify vulnerable areas and stop its degradation but also to assess the effectiveness of any potential soil regeneration program. At large scales, monitoring SOC changes usually depends on soil surveys conducted in a top-bottom approach, with a single publicly funded organisation in charge of organising and executing the survey. This centralised framework is cumbersome and has led to a dearth of data that prohibits a regular assessment of soil threats at the national and global scale. At the local scale, farmers and land managers need to routinely survey their properties in order to measure changes in soil condition. Detailed maps are required to adequately apply management practices, comply with environmental regulations and provide accurate carbon sequestration estimates if they decide to participate in carbon credits schemes. However, despite the many methodological and technological developments in soil sciences and related fields, the current in-farm cost of accurately measuring changes in soil remains a barrier to the widespread adoption of practices such as carbon sequestration. The aforementioned problems arise due to the disconnection between local and global or national scales, thus, the challenge is to improve the data and model connectivity between them. Here we present examples of modelling techniques that integrate these working scales to generate synergy and obtain benefits at all levels. Specifically, a) how to effectively integrate local data of dynamic properties such as SOC to inform policies at national or global level without compromising user's privacy and b) how local users can benefit by using global/national models to potentially reduce the data requirements and cost of assessing carbon.

<sup>4</sup> Leibniz Centre for Agricultural Landscape Research (ZALF), Müncheberg, GERMANY

Understanding the impact of soil functions on crop growth is crucial for transitioning to a sustainable bioeconomy. It's essential to explore how agricultural management can improve efficiencies by targeting soil functions and whether such improvements are possible regardless of soil considerations. To this end, this study presents a systematic literature review on indicators for resource use efficiency in agricultural soil management, defined as the ratio between benefits generated by agricultural production processes and the resources used. Our focus encompasses cropland and pasture management within mixed farming systems, excluding livestock husbandry and greenhouse based horticulture. The review considers quantifiable benefits such as crop yield, financial gains, and embodied carbon or energy, alongside inputs like production costs, fertilizer, land area, fossil energy, or water. Employing keyword searches in Web of Science, Scopus, and Google Scholar, we narrowed down 18,400 results to 266 relevant English journal articles published from 2009 to 2023, excluding conference papers. In the Scopus search, we employed terms like 'efficien\*' within title, 'indicator and agricultur\*' within title, abstract, and keyword. Similarly, in Web of Science, our search criteria involved 'efficien\*' within title and 'indicator,' along with 'agricultur\*' within the topic. Regarding resource use efficiency indicators in agricultural soil management, our evaluation considered whether articles addressed agricultural practices, explored connections with resource use efficiency indicators, scrutinized soil functions, and examined interrelationships among different resource use efficiency indicators. We categorized the information extracted from the review into six primary indicators (benefits) groups: aboveground biomass, embodied energy, embodied nitrogen, financial benefits, yield, and sequestered carbon. Each group comprises subdivisions (inputs), resulting in a total of 25 fact sheets that offer definitions and descriptions of the indicators, their correlations with soil management, and insights into their strengths and weaknesses concerning impact area measurement. This dataset serves as a comprehensive toolbox for researchers, enabling them to identify indicators aligned with their specific research requirements.

**DROUGHT RESILIENCE CALCULATOR: A TOOL FOR FARMERS AND SUSTAINABILITY SPECIALISTS**

C. MORGAN, K. FLYNN, D. BAGNALL, C. MOLLING

Soil Health Institute, Morrisville, USA

Natural climate solutions are essential in fulfilling commitments made in the Paris Agreement, accomplishing UN Sustainable Development Goals, and ensuring sustained and responsible use of natural capital for future generations. While the benefits of adopting regenerative agricultural practices have been well documented, our ability to quantify the impacts of management-induced changes on dynamic soil properties, such as plant-water relations, is limited. For example, previous equations in soil science studies have not accurately represented the positive relationship between management-induced increases in soil organic carbon and plant available water holding capacity (AWHC). Our work uses a pedotransfer function that predicts changes in AWHC that occur from changes in organic carbon that result from adopting reduced tillage practices. This pedotransfer function is being developed into a decision support tool to provide farms and soil managers with locally relevant, benefit-relevant, information on additional water they could expect for crop growth during the growing season if they reduce tillage and increase organic matter. The same tool is being made adaptable to account for these improvements in water availability for supply sheds and sustainability commitments by buyers of agricultural products.

##### PARTNERSHIPS SCALE SOIL HEALTH PRACTICE ADOPTION AND MITIGATE CLIMATE

A. WICK

Syngenta Group, West Fargo, USA

As sustainability goals are developed across industry, we look to the science for robust solutions and education to implement new practices on-farm. Bringing groups working in these areas together in a meaningful way is critical to support the entire system for the desired outcome of climate mitigation. Challenges include, designing research studies and soil assessment methodology to support measurement of practice changes and confidence in claims. Also, internal science- and logistics-based upskilling of companies and other organizations working on climate to ensure the skillsets are developed to support practice adoption and develop meaningful goals. Lastly, consistency in communication of these results to growers who are embracing practice change is critical. It is not reasonable to work in silos, therefore, intentional development of partnerships is needed. We will provide real-world examples of how industry, research institutes and grower-facing organizations are working together to have impact.

Agroecosystem management impacts long-term sustainability of crop production and soil health. Soil organic C is an overall soil health metric and an important greenhouse gas sink for mitigating climate change. Long-term studies are critical in determining the overall impact of conservation management practices. Here, we characterized the impacts of 71 years of cultivation on surface soil carbon (0-12") at three long-term sites in Akron Colorado, Big Spring Texas, and Moccasin Montana, which span a broad climatic gradient. Sites at Big Spring and Moccasin lost 14-30% SOC and N since 1947. Conversely, SOC increased by 16% at Akron, likely due to the inclusion of conservation management practices such as no-till and continuous cropping. Stable isotope values for SOC shifted to a more C3 signature, reflecting long-term inputs from C3 crops such as cotton, wheat, and other small grains. Interestingly, over seven decades, soil textures changed, which was an unexpected result given that texture is considered a stable inherent soil property. Soil organic carbon was related to changes in percent silt+clay at all sites. A decrease in SOC was correlated with a decrease in silt+clay content at Big Spring. However, the decrease in SOC at Moccasin was correlated with and an increase in silt+clay content. Together, these results suggest changes in physical properties over time, perhaps due to erosion or deposition, will contribute substantially to SOC stock changes. Estimates of soil C storage potential that rely on soil texture will need to account for changes over time. Best-management practices, such as no-tillage and implementation of continuous cropping at these sites will be critical in maintaining soil health.

##### THE ISRIC WORLD SOIL REFERENCE COLLECTION: A UNIQUE RESOURCE

S. MANTEL

ISRIC World Soil Information, Wageningen, THE NETHERLANDS

From 1966 onward, ISRIC has established a reference collection and collects, documents, studies the soils of the world, contributes to standards for analysis, description and classification and provides a global overview of soils and their properties. The ISRIC World Soil Reference collection consist of: 1100 soil monoliths (undisturbed sample from a profile wall and conserved with lacquer and glued to a board for display in our museum) from over 75 countries, 5000 soil samples with physical and chemical data, 3500 thin sections, photographic documentation of soil (site and soil profile). These samples have been collected and analyzed in a consistent way, according to international standards and 75% are considered reference soils: complete descriptions, monoliths with accompanying sample material, data from certified, reference lab, characteristic of the map units of the FAO Soil Map of the world.

The ISRIC soil reference collection provides: 1) a reference for (evolving) soil international classification systems (definition and verification of criteria), 2) a basis for research on soil formation, soil properties and soil functions and methodology development, and 3) a unique source for education and advocacy.

The reference collection is used for a wide variety of purposes across the world. Examples are: 1) creation of a global reference IR-spectral library for various soil attributes (ICRAF, Kenya), 2) estimation of soil organic carbon from smartphone images and soil color, 3) comparison of pre- and post-Chernobyl soil conditions in the Middle East (ICARDA, Syria) to assess the impact of nuclear fall-out on soils, 4) research on cesium behavior in a variety of soil types throughout the world by UCL (UCL, Louvain-la-Neuve, Belgium), assessment of soil biota richness and composition through assessment of soil DNA.

Key words: reference collection, monoliths, samples, global

### CONTRASTING NITROGEN SOURCE IMPACTS ON NITROGEN USE EFFICIENCY AND SOIL HEALTH UNDER SILAGE CORN PRODUCTION IN A SEMI-ARID ENVIRONMENT

J. NORTON, P. MILLER

Utah State University, Logan, USA

Silage corn production challenges sustainable intensification and soil health in semi-arid environments because the entire aboveground biomass is harvested and removed from the field. An irrigated silage corn field study was conducted for over a decade comparing nitrogen fertility sources using a complete randomized block design with four treatments: control with no nitrogen fertilizer, low ammonium sulfate at 112 kg N/ ha (AS100), high ammonium sulfate at 224 kg N /ha (AS200), and steer manure compost at 224 kg total N/ ha (compost). Research focused on the impact of these contrasting nitrogen sources on silage corn production, nitrogen use efficiency (NUE), N cycling and soil health indicators.

Variable responses in yield, NUE, and soil health indicators across years emphasized the importance of multi-season studies. Yield under compost treatment exhibited a notable 41% increase compared to control but was approximately 31% lower than the average yield under AS100 and AS200 treatments. AS100 achieved a yield comparable to AS200 and demonstrated higher NUE, challenging conventional belief that increased nitrogen applications ensures maximum yield and profitability.

Despite lower yield and NUE, the compost significantly enhanced soil total nitrogen and soil organic carbon by 23%. Multiple soil health indicators increased with strong positive correlations between carbon and nitrogen indicators. These observations highlight interactions between soil carbon and nitrogen and the responsiveness of active organic matter pools and enzyme activities. The nitrifying microbiome was affected by ammonium sulfate fertilizers with increases in both abundance and activity of the ammonia oxidizing bacterial communities in contrast to the response to composts. While AS fertilizers proved effective in achieving higher silage corn yields and NUE compared to compost treatment, compost enhanced soil C and N and soil health indicators. These positive shifts underscore the advantages of combining compost with fertilizers for sustainable soil management. Farmers are encouraged to adopt a balanced approach, incorporating compost alongside commercial fertilizers and implementing soil health practices for sustainable silage corn systems.

HIGHER THAN EXPECTED: NITROGEN FLOWS, BUDGETS, AND USE EFFICIENCIES OVER 35 YEARS OF ORGANIC AND CONVENTIONAL CROPPING

K. JAROSCH <sup>1</sup>, A. OBERSON <sup>2</sup>, E. FROSSARD <sup>2</sup>, A. HAMMELEHLE <sup>1</sup>, A. FLIESSBACH <sup>3</sup>, P. MÄDER <sup>3</sup>, J. MAYER <sup>1</sup>

<sup>1</sup> Agroscope, Zurich, SWITZERLAND

<sup>2</sup> ETH Zurich, Zurich, SWITZERLAND

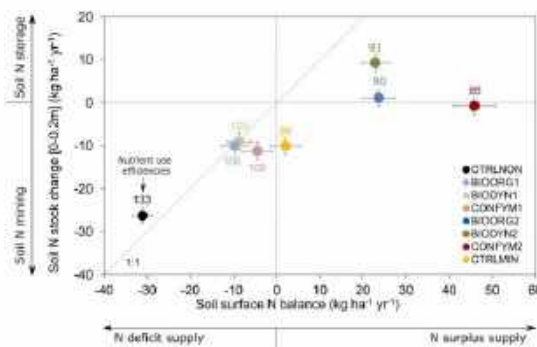

<sup>3</sup> FiBL Switzerland, Frick, SWITZERLAND

Organic and conventional cropping systems differ in type and amount of nitrogen (N) inputs. In organic cropping only organic fertilizers are permitted, while both organic and mineral fertilizers are used in conventional cropping. Fertilizer type and amount can affect N use efficiency of a cropping system, but contributions via symbiotic N fixation and changes in soil N stocks are rarely quantified based on field data when computing nutrient budgets.

We calculated an N budget that accounts for these contributions based on annual data records for a period of 35 years at the Swiss DOK field experiment. Different organic and conventional cropping systems have been maintained at two fertilization levels: typical for the respective system, and half these doses (low). In each of the 7-year crop rotation periods, legumes (grass-clover ley, intercrops, soybean) were grown in three years. Their symbiotic N fixation was quantified based on 15N studies and legume N yield data. Soil surface budgets (sum of N inputs from fertilization, symbiotic fixation, seeds, and deposition minus N outputs via crop harvests) yielded balances from -31 kg N ha<sup>-1</sup> yr<sup>-1</sup> (in non-fertilized control) to +46 kg N ha<sup>-1</sup> yr<sup>-1</sup> (conventional system with typical fertilization level).

Nitrogen use efficiencies (NUE; N output with harvests as % of sum of N inputs) reached values >100 % in treatments with negative balances while NUE ranged from 85 % to 99 % in treatments with positive balances. Changes in topsoil (0–0.2 m) N stocks over time ranged from -26 to +9 kg N ha<sup>-1</sup> yr<sup>-1</sup> and declined in both unfertilized and mineral fertilized controls, and in systems receiving animal manure at low fertilization levels.

Thus, positive soil surface N balances and animal manure are needed to maintain or increase topsoil N stocks. While NUE was generally high in all cropping systems there remains a trade-off between either soil N mining at higher NUE or potential N loss to the environment at lower NUE.

##### PHOSPHORUS ADDITION IS REQUIRED FOR IMPROVING SOYBEAN-RHIZOBIA INTERACTIONS AND RATES OF NITROGEN FIXATION

H. WALLING<sup>1</sup>, S. ROTHWELL<sup>1</sup>, J. QUINTON<sup>1</sup>, M. RUFINO<sup>2</sup>, P. HAYGARTH<sup>1</sup>

<sup>1</sup> Lancaster University - Lancaster Environment Centre, Lancaster, UNITED KINGDOM

<sup>2</sup> Technical University of Munich - TUM School of Life Sciences, Munich, GERMANY

The capacity of soybean to fix atmospheric nitrogen (N<sub>2</sub>) through its interaction with rhizobia in the soil microbiome is driven by the multistep process of nodulation, successful nodule development and successful nodule function. Demand for soybean production is continuing to increase, one potential way to meet this demand is through improved N<sub>2</sub> fixation efficiency, we are suggesting this can be achieved by optimising phosphorus (P) fertiliser use. Phosphorus is an essential nutrient for nodule formation and function, with adequate P supply being required to optimise N<sub>2</sub> fixation and improve soybean yield.

We examined the influence of P fertiliser addition on soybean nodulation, nitrogen fixation and yield following inoculation with USDA 110 in a greenhouse trial, with harvests completed at the R1 (beginning flowering), R3 (beginning pod formation), R5 (beginning seed filling) and R7 (beginning of full maturity) growth stages, to address the following hypotheses:

1. Phosphorus addition will increase soybean nodulation across soybean growth stages, with N<sub>2</sub> fixation peaking at the R3 growth stage.
2. Through increasing N<sub>2</sub> fixation phosphorus addition will increase biomass production, leading to increased grain yield at the R7 growth stage.

Through addressing these hypotheses, we aim to address potential mechanisms driving improved N<sub>2</sub> fixation through the study of plant photo-efficiency, nodule leghaemoglobin concentration, and plant-soil nutrient partitioning.

Results of preliminary experimental work found a ~20% increase in N<sub>2</sub> fixation following P addition, resultant from a significant increase in nodule number and dry weight. Work is currently ongoing, and results will be presented at the symposium. The results of this study will enable better mechanistic understanding of the role of P in improving soybean N<sub>2</sub> fixation, allowing for improved nitrogen use efficiency and crop productivity.

##### INTEGRATING ALFALFA (MEDICAGO SATIVA L.) INTO ANNUAL CROPPING SYSTEMS TO ENHANCE SOIL MICROBIOME DIVERSITY AND NUTRIENT CYCLING

M. BERTI <sup>1</sup>, H. BUECKING <sup>2</sup>, S. BAUDER <sup>3</sup>

<sup>1</sup> NORTH DAKOTA STATE UNIVERSITY, Fargo, USA

<sup>2</sup> UNIVERSITY OF MISSOURI, Columbia, USA

<sup>3</sup> SOUTH DAKOTA STATE UNIVERSITY, Beresford, USA

Alfalfa or lucerne is a perennial legume forage with the ability of fixing large amount of atmospheric N<sub>2</sub> through symbiosis with rhizobia. Crops planted after termination of alfalfa can benefit from the nitrogen mineralized from alfalfa, reducing the need for chemical fertilizer. Alfalfa is colonized by arbuscular mycorrhizal (AM) communities which have an important role in providing nutrients to alfalfa. The objectives were: 1) to determine the AM fungal colonization in alfalfa production systems in North Dakota (ND) and South Dakota (SD) and the factors affecting AM colonization rate; 2) to determine alfalfa variety and K fertilizer rates influence on AM fungal colonization and proliferation; 3) to identify AM community composition in alfalfa roots in intercropping with corn, and 4) to identify the impact of AM fungal additives on the AM community composition of alfalfa. Several experiments were established in both states between 2020 and 2023. In 2021, alfalfa roots were sampled at 30 locations in ND and 22 locations in SD. The AM fungal colonization ranged from 12 to 88%. Plant density, grazing, and irrigation affected AM colonization. For the second objective, three different varieties and K treatments were applied: 0, 168, and 336 kg K<sub>2</sub>O/ha in single- and split-application. Total seasonal forage yield was significantly lower when no K was applied. All plants showed similar AM colonization rate of 50 to 60%. In Objective 3, alfalfa was grown alone or in intercropping with corn and two row spacings. Corn grain yield decreased only with the wider row spacing. Intercropping did not have an effect on the colonization or diversity of the AM community composition of alfalfa. The AM fungal communities were mainly represented by species of the family Glomeraceae (*Funneliformis*, *Septoglomus*, *Glomus*, *Rhizophagus*) with mean relative abundances ranging from 68% to 100%. Fungal additives did not increase yield or nutritive value of alfalfa but increased abundance of AM in the Glomeraceae family.

The soils in the Western Balkans (WB) are under pressure due to rising demands for food, feed, and energy supply. Soil degradation in the (WB) poses a transboundary issue, necessitating responsible engagement from all stakeholders to ensure sustainable soil management in alignment with the goals of the 2030 Agenda for Sustainable Development.

The Soil Partnership for the Western Balkans (WBSP) commenced in 2021 under the leadership of the Regional Rural Development Standing Working Group in South Eastern Europe (SWG). Serving as an open forum, the partnership facilitates the gathering of all stakeholders in the region to discuss and exchange knowledge, data, best practices, and experiences related to sustainable soil management. The Western Balkans Soil Partnership was formally established in December 2022 with the aim of preserving, protecting, and restoring soils in the Western Balkan region. Participating countries include Albania, Bosnia and Herzegovina, Kosovo, Montenegro, North Macedonia, and Serbia, despite differences in developmental stages. The formation of such a partnership is justified, given that the region shares common economic and social challenges, as well as a similar cultural and scientific heritage.

Despite being endowed with some of Europe's most fertile soils, the Western Balkans soil is facing natural constraints such as salinity, sodicity, acidification, poor drainage, texture conditions, shallowness, stoniness, and other nature-based and human-induced limitations. The expert group formed by SWG initiated various short and long-term activities within the partnership, including a general assessment of available data, identification of drivers affecting soil quality, analysis of primary soil degradation processes, capacity assessment for each country in dealing with sustainable soil management, and identification of best soil management practices. Other initiatives include the establishment of a GIS-based regional soil map and information system, a soil monitoring system throughout the region, and the creation of the Western Balkans Soil Museum. These endeavors aim to address the shared challenges in policy reform, harmonization, information systems, economic development, and limited institutional capacity across the region.

Living Labs (LLs) are dynamic ecosystems in which stakeholders interact to co-create innovations to reach joint objectives within real-world environments at territorial, landscape, or regional scale. In Europe, about 2/3 of the soils are estimated to be unhealthy (EUSO, 2023). The connections established between soil science, policy, and stakeholders in LLs could provide a pathway for a more sustainable soil management by maintaining and restoring soil health as aimed by the EU and the new Soil Monitoring Law. The present study explores the integration of LLs into soil research over the past decade through a systematic literature review and presents a local case study in South Tyrol, Italy. Results revealed that, among over 3000 works published on LLs in the last 10 years, only about 3% were inherently related to soil. While majority of them are still within EU, there is an evident expansion towards Sub-Saharan Africa, Oceania and Asia in most recent years. Findings also indicate a great interest in soil related research in LLs (67%, n=41), followed by reviews (26%, n=16) and limited number of editorials (n=4) & keynote papers (n=1). Our findings highlight the potential of LLs to assess local soil health issues (e.g. above-below ground biodiversity, C stocks, pollution) ensuring feasible solutions and innovations applicable in the real-world conditions. In our South Tyrolean LL case study, we address the local need of carbon sequestration, C stock conservation and improved nutrient management by applying different cover crops in apple orchards. This case study illustrates a successful implementation of a sustainable, long-term management approach that embraces stakeholder interaction (scientists-farmers-apple consortium) at a regional scale. Through such collaborations, collective efforts can address real-world challenges with greater speed and efficiency.

Healthy soils provide an abundance of ecosystem services (e.g. food provision, water storage and purification, biodiversity conservation, climate change mitigation, cultural heritage). However, human activity and environmental changes may impact the provisioning of ecosystem services and driving soils into an unhealthy state. Linking these aspects requires a systems perspective of the human-environment interactions related to soils. In this context, we define soil needs as the requirements from existing and emerging socio-economic and geo-biophysical perspectives that determine soil health and related services to human society. The aim of the study was an assessment of soil needs in the natural and the socio-economic system via validation from stakeholders. Socio-economic and soil system interactions are subject to strong regional variations. Hence, we consider systems in agricultural, forestry, urban and (post-)industrial, and mixed land uses. Within the land uses we selected 20 representative regions across Europe and applied the SNA. The SNA is based on the Driver-Pressure-State-Impact-Response (DPSIR) framework which categorises human-environmental system interactions in drivers for decision-making on land use and soil management (pressures), the current state of ecosystems, the impacts on ecosystem services and governance, policy, and management options for soil health improvements. Methodologically, the SNA combines natural science knowledge on the functioning of soils and ecosystem services, with social science research methods (participatory workshops and qualitative interviews). Our results disclose the drivers of soil health dynamics, which are characteristic for regionally specific combinations of economic conditions, policy, land use history, land managers perceptions and geophysical and climatic conditions. The results are abstracted to a land use level along the categories of the DPSIR framework.

##### DECISION-MAKING PRACTICE OF IMPLEMENTING AN INTEGRATED URBAN ENVIRONMENTAL CONTROL SYSTEM IN A RAPIDLY INDUSTRIALIZING CITY

J. TAMÁS, L. STÜNDL, E. HARSÁNYI, A. NAGY

University of Debrecen, Debrecen, HUNGARY

Global investors have been looked for new investments, relying on the significant ability of the Hungarian state to improve cross border capital raising. The investments were mainly implemented in new industrial parks, which fundamentally changed the urban landscape and land use in large urban areas. The city of Debrecen, which is the second largest city (total area 365 km<sup>2</sup>) in Hungary, is a typical example of similar urbanization processes worldwide.

The implementation of new unknown technologies, such as soil / land use and water management related to the automotive industry, has increased the lack of knowledge and, in part, uncertainty among the population. In addition to increasing the environmental security of the population, the goal of the city stakeholders is the sustainable development of integrated green-blue infrastructure. The first part of CIVAQUA Hungarian project providing the largest ecological water supply, has already been realized till end of last year, where the water of the Tisza River was utilized in this water-poor urban environment, revitalizing the wetlands of the Tóció creek in its urban catchment. A new interdisciplinary, environmental decision-making forum was established, where city leaders, scientists of the University of Debrecen, representatives of relevant authorities and representatives of the population developed and implemented the Environmental Control System. This industrial sector independent new control system includes not only soil, water, biodiversity, and air noise resources, but also law and IT working groups. It identified common reference sampling points, measuring base stations and additional specific points for specific resources such as soil and water, depending on topography, climate, soil type and land use. The necessary methods of investigation and method of interpretation were also adapted based on sites

The research work supported by Hungarian TKP2021-EGA/TKP2021-NKTA fund.

Healthy and carbon rich soils are an essential part of the solution to some of today's most existential issues, including climate change, biodiversity decline and food and water insecurity. Approaches like agroecology can increase soil organic matter storage and improve soil health and ecosystem functioning and, hence, help to mitigate and adapt to climate change, secure biodiversity and enhance food security. While most farmers are genuinely motivated to safeguard and nurture their land, the adoption of sustainable soil management practices necessitates policy interventions and the availability of trusted, locally relevant information to create the right enabling conditions supporting farmers, especially, but not only, in the transition phase. Simultaneously, decisions should be based on a combination of scientific insights and traditional knowledge pertaining to soil processes and socio-economic contexts. Collaborative programmes must be crafted together with the practitioners on the ground. For almost a decade, the international "4 per 1000" Initiative has been striving to facilitate the dialogue and cooperation between government and non-governmental agencies, scientists, farmers and other stakeholders to share evidence-based best practices and develop solutions at all levels. Approaching a decade of the "4 per 1000" Initiative offers the perfect opportunity to reflect on the evolution of our understanding concerning the contribution of enhancing soil carbon and soil health to meeting global challenges as well as on successful strategies and further needs for action in the years ahead.

##### INNOVATIVE AND SUSTAINABLE MODELS FOR SOIL HEALTH: A LIVING LAB FOR THE DEVELOPMENT OF A SUSTAINABLE AGRICULTURE IN LOMBARDY (ITALY)

P. IAVAZZO, E. TAGLIAFERRI, L. VERDELLI, S.R. MOTTA

ERSAF, Milan, ITALY

In recent years, deep structural changes affected Lombardy agriculture: the reduction in the number of farms and total agricultural land, the increase in average farm size and the progressive concentration of livestock farms. This intensive management system, based on high use of external inputs and modest crop diversification, impacted the environmental matrices. Furthermore, the agronomic use of manure, although supplying beneficial substances to soil and promoting less use of synthetic fertilizers, requires careful management to prevent negative environmental impacts.

European policies push towards an agriculture model sustainable, productive and able to provide environmental services. A recent tool for the consolidation of training, knowledge sharing and demonstration actions is represented by Living Labs, based on the interaction and collaboration between different actors involved for the application of innovative solutions. In this scenario, local authorities, through knowledge of the territory and direct relations, play a prominent role acting as “brokers”, recording knowledge needs and existing barriers to their dissemination and aggregating stakeholders at different levels.

In 2022 ERSAF, technical agency of Lombardy Region dealing with agricultural services, founded the Living Lab (LL) “Innovative and sustainable models for soil health” with Università Cattolica del Sacro Cuore and Università degli Studi di Milano. The objectives were to calibrate and introduce sustainable management practices within intensively managed agricultural lands of Po Valley and to monitor, report and verify agroecosystem performances towards healthy agricultural soils. This goal will be achieved through a multiactor approach, involving farmers, researchers and other stakeholders, especially focused on the development of conservative management practices, associated with preservation and increase of soil organic carbon content in connection with EU MISSION “A Soil Deal for Europe” objectives related to Carbon Farming and on the resources management. In addition, complementary activities aimed at the improvement of innovative and sustainable soil management models can be developed. Currently the LL is composed by 1 Long Term Experiment, 9 Lighthouse Farms and a growing number of partners.

##### 25 YEARS OF SOIL PROTECTION IN SWITZERLAND: A MIX OF HARD LAW, SOFT LAW AND COMMUNICATION

E. HAVLICEK, G. SCHWILCH

Federal Office for the Environment - Soil Section, Berne, SWITZERLAND

Soil is at the centre of competing uses and obviously, sustainable soil management involves a multitude of stakeholders. Developing and implementing a coherent policy is complex and difficult – but not impossible. Two examples from Switzerland illustrate the process of developing soil policies and implementing sustainable soil management. In many cases, the use of a mix of approaches (smart regulation, see figure) and cooperation between the stakeholders will allow for a more effective soil protection.

(1) Specific protection against physical soil threats was included into law in 1989, however, a legal framework is not sufficient for an operational implementation. Establishing the instrument of “specialists of soil protection on construction sites” has required a long development process and collaboration between a number of stakeholders. The effective implementation has involved different levels of regulation (hard law, soft law, voluntary instruments) and has demonstrated the effectiveness of a smart regulation approach. Along with the legal requirements and the scientific input, a strong and long-lasting collaboration with the Swiss Soil Science Society, which brings together scientists, policy makers and practitioners, was decisive in achieving this success.

(2) Sustainable soil management depends on environmental factors and management practices, and is underpinned by the interaction of its physical, chemical and biological components. So far soil policies struggle to integrate this complexity into legal instruments. In Switzerland, the creation of a networks of scientists and policymakers in the field of biological, chemical and physical soil protection has enabled direct exchange of strategical information (balance between policy needs and possible scientific results) and the design of several applied research projects. Cooperation carried out for over 30 years by the working groups that include representatives of federal and cantonal administrations and research institutions has proven to be an effective approach in designing soil policies and in contributing to the (ongoing) process of revising the current law on soil protection.

**SOIL SCIENCE AND POLICY IN AUSTRALIA: INFLUENCING FROM THE GROUND UP, DOWN UNDER**

A. BAGNARA

<sup>1</sup> MA Marketing Communications, University of Canberra, CANBERRA, AUSTRALIA

<sup>2</sup> Marketing Communications Manager, Soil Science Australia, MELBOURNE, AUSTRALIA

This case study provides insight into how the creation of trusted and committed relationships between scientists and policy makers enables robust development and effective implementation of public policy.

Australia's former National Soils Advocate, the Hon Penelope Wensley AC, promoted such a partnership, resulting in the Parliamentary Friends of Soil (PFOS) group being established in 2020.

Strong links with parliamentarians created momentum for increasingly effective networking events and other opportunities for influence.

PFOS is a non-partisan forum for parliamentarians to meet and interact with soil scientists and researchers, policy-makers, farmers and land managers, industry representatives and stakeholder groups on matters relating to the health and maintenance of Australia's soils.

The group was re-established under the 47th Australian Parliament ahead of World Soil Day 2020, by which time membership had more than doubled to 24 members.

The role of the National Soils Advocate was discontinued in August 2023. However, the former Advocate continues influencing in her long-held roles as Patron of both Soil Science Australia and the Australian Cooperative Research Centre for High-performance Soils.

Many initiatives established under the former Advocate are now being advanced by the broader soil community in Australia.

Soil Science Australia is driving ongoing engagement with PFOS. The World Soil Day networking event at Parliament House in 2023 was backed by 15 government and non-government supporters.

Hear how Soil Science Australia is engaging with PFOS to position the critical findings of soil science and promote soil health as a significant and leading consideration for policy in Australia.

##### CULTIVATING SUSTAINABLE SOIL MANAGEMENT: FAO'S GLOBAL SOIL DOCTORS PROGRAMME IN ACTION

C. OLIVERA, C. FERRO, J. NABWAMI, J. REY BRINA

Food and Agriculture Organization of the United Nations, Rome, ITALY

The Global Soil Doctors Programme of the Food and Agriculture Organization of the United Nations stands at the forefront of promoting sustainable soil management worldwide. This presentation showcases the Programme's pivotal role in fostering collaboration and equipping farmers with essential tools for soil assessment.

Operating in 15 countries across Africa, Latin America, the Caribbean, Asia, and Eurasia, the programme has successfully trained 611 trainers, empowered 1400 soil doctors and over 7500 farmers. Its adaptability to local conditions is underscored by collaborative partnerships with national stakeholders and the translation of training materials into local languages. To date, materials have been translated to more than 18 languages, further increasing accessibility and impact. This initiative, spanning academia, government, private sectors, and farmers, signifies a harmonious global approach.

The success of the programme lies in bridging the gap between scientific knowledge and practical implementation. Collaboration with academia enriches training with theoretical insights and innovative practical exercises, while government support integrates sustainable soil management into local policies. Participation in collaborative projects and partnerships with organisations strengthens the commitment to holistic solutions. Private sector participation not only helps sponsor activities but also brings their technical expertise, amplifying the programme's impact.

The farmer-to-farmer training model, emphasizing hands-on learning, has empowered individuals and garnered community recognition, ensuring its continuity. This practical approach ensures not only knowledge acquisition but also internalization, deepening the understanding of sustainable soil management. The programme's impact is assessed through valuable trainee feedback, focusing on methods' effectiveness and trainees' and Soil Doctors capacities for informed decision-making in sustainable soil management.

The presentation will feature captivating videos to demonstrate the programme's impact, inviting audience input and fostering increased collaboration with soil science societies. The presentation will delve into the importance of collaborative models, emphasizing the bridge between scientific knowledge and grassroots application. As we share insights from the programme's implementation, we invite engagement, to meet the evolving needs on the front lines of sustainable agriculture.

<sup>1</sup> Centre wallon de Recherches agronomiques - Unit of Soil, Water and Integrated Crop Production, Gembloux, BELGIUM

<sup>2</sup> Agroscope - Department of Agroecology and Environment, Zürich, SWITZERLAND

<sup>3</sup> Council for Agricultural Research and Economics - Research Centre for Agricultural and Environment, Rome, ITALY

Healthy soils are fundamental to sustain agri-food systems. Intensive farming practices and global changes profoundly affect agricultural soils across European regions, causing a loss of biodiversity, a decline in organic matter content, and heightened susceptibility to erosion. To counteract this dynamic, it is essential to implement policy measures related to protection and soil restoration at all levels, from local to global.

Recognizing these challenges, some farmers are embracing agro-ecological innovative approaches to enhance soil quality, as conservation or organic farming, or other specific regenerative practices adopted in conventional farming. But the diffusion and adoption of these innovations does not always go as planned by policy makers. Economical and climatic uncertainties inherent of these socio-ecological systems make their management complex. Choices, decision-making processes and practices of farmers are based on both objective and, to some extent, subjective, value-laden elements, influenced by their own history, worldviews and knowledge.

This study aimed at documenting the adoption process of innovative soil management practices related to conservation agriculture in twenty European countries involved in the EJP SOIL i-SoMPE project by applying an original methodological approach inspired by social sciences. Qualitative open-ended interviews of main stakeholders were done by partners in each country involved in the project. Data collected were processed using cognitive mapping, which makes it possible to combine qualitative and quantitative techniques.

We explore the barriers and opportunities to the diffusion and adoption of practices linked to conservation agriculture. Our results highlight the importance of networks between stakeholders. The smooth running of these networks is of interest for many factors, among which the most important is related to the knowledge production, availability and sharing between farmers and with advisors and researchers. The others important factors are linked to financial incentives coming from a safe economic and policy environment, involving policy makers and local administration, and the adequate availability of machinery adapted to local pedo-climatic conditions, involving, among other, industrial actors.

**LASOL: A LIVING LAB TO HELP INTEGRATE SOIL PROTECTION INTO SPATIAL PLANNING AND CONSTRUCTION**

F. FAVRE BOIVIN, S. VANBUTSELE, A.-. COSANDEY, D. MARTIN, J. FALQUE, J. RIONDEL

University of Applied Sciences and Arts of Western Switzerland, Fribourg, SWITZERLAND

In Switzerland, despite numerous detailed tools to help apply soil protection in construction, there is a lack of application of good practice. In the area of land use planning, only land classified for its production potential is strongly protected. However, the swiss soil strategy has set clear objectives, including integration of soil value into spatial planning and elimination of persistent soil damage such as compaction. Soil protection working groups note that these objectives have largely not been achieved. Why this failure? What are the obstacles and the needs of the various stakeholders? Where are opportunities for soil protection?

A living lab has been set up to answer these questions. It is focusing on a 60-hectare land development project called Chamblieux-Bertigny, in the Canton of Fribourg. The project comprises the construction of a hospital, a motorway cover, a neighborhood development and an urban park. These different projects are at very different stages of the process, and are not under the control of the same project owners. LASOL brings together project owners, soil protection supervisory bodies, spatial planning and soil specialists, and facilitators.

The project aims to identify the key moments for soil protection in the timeline of the various projects, to develop a common lexicon for talking about projects and soil, to identify the key people and their needs, so that soil protection and the transfer of information can take place through the stakeholders. Finally, existing tools are evaluated or new tools are developed to help achieve these objectives.

6 months of LASOL's life have revealed first stumbling blocks: the lack of mutual understanding of the fields specific languages, their processes and the levels of constraints relating to the decision-making stages. The second difficulty lies in the different timeframes of the projects, despite the fact that they cover the same territory. Mapping tools are proposed to both identify the difficulties and attempt to resolve them among them Soil quality index tools.

CONNECTING STAKEHOLDER KNOWLEDGE TO SUPPORT EUROPEAN AND NATIONAL POLICY DEVELOPMENT FOR CLIMATE-SMART AND SUSTAINABLE SOIL MANAGEMENT

A. BESSE-LOTOTSKAYA<sup>1</sup>, C. CHENU<sup>2</sup>, S. VISSER<sup>3</sup>, R. GERASINA<sup>2</sup>, B. HELGHEIM<sup>4</sup>

<sup>1</sup> Environmental Sciences, Wageningen University & Research, Wageningen, THE NETHERLANDS

<sup>2</sup> UMR ECOSYS, Joint research unit INRAE, AgroParisTech, Université Paris-Saclay, Paris, FRANCE

<sup>3</sup> Climate KIC, Amsterdam, THE NETHERLANDS

<sup>4</sup> Environment and natural resources, NIBIO, As, NORWAY

As part of the European Green Deal and EU soil and biodiversity strategies, European Commission is developing policies and solutions for soil health and climate-smart sustainable agriculture such as EU Soil Monitoring and Resilience Directive and EU Carbon Removal Certification framework. Member States will need to implement these policies and fit them into national policies and schemes. A broad spectrum of stakeholders is crucial for this process, including European, national and regional policy makers, researchers and practitioners. The European Joint Programme, EJP SOIL (Towards climate-smart and sustainable agricultural soil management), developed an innovative instrument to effectively incorporate soil research in practice and policy solutions within 24 participating countries, to connect stakeholders with each other and to the European science-policy-practice arena.

The network of committees of soil stakeholders, called National Hubs, were established in 2020. National Hubs are mostly led by a ministry that is responsible for agricultural soils and consists of farmers, farmers advisors and farmers organisations, industry and agrobusiness, NGOs, local or national governance and policy implementing representatives, scientists. National Hubs (i) provide feedback to the EJP SOIL activities and outputs and support the dissemination of EJP SOIL outcomes, (ii) voice national position and needs, and (iii) contribute to and learn from the work done in research.

The analysis of the functioning of the National Hubs reveals multiple modes of functioning (size of the hub, frequency of meetings, topics of discussion, level of engagement) that is related to historical developments and cultural aspects of a specific country. This analysis allows to identify the factors of success of such instruments. Despite of the heterogeneity, National Hubs have proved to achieve the joint objective and are a successful instrument for supporting European and national policy development, on which current soil related initiatives can build upon.

#### ENHANCING AGRICULTURAL SUSTAINABILITY THROUGH LONG-TERM CROP ROTATION: INSIGHTS FROM A 128-YEAR OLD COTTON ROTATION EXPERIMENT

A. GAMBLE, D. DELANEY, C. MITCHELL, J. BURCH

Auburn University, Auburn, USA

Established in 1896, Auburn University's Old Rotation is the United States' oldest ongoing cotton (*Gossypium hirsutum* L.) experiment. This experiment has been instrumental in documenting the long-term impacts of crop rotation and winter cover cropping on crop productivity in the highly weathered soils of the southeastern United States. Treatments at the Old Rotation consist of 1) continuous cotton with no winter legume cover crop and no nitrogen fertilizer, 2) continuous cotton with a winter legume cover crop but no nitrogen fertilizer, 3) continuous cotton with no winter cover crop but with nitrogen fertilizer, 4) cotton-corn rotation with a winter legume cover crop but no nitrogen fertilizer, 5) cotton-corn rotation with a winter legume cover crop and nitrogen fertilizer, and 6) a three year rotation of cotton, winter legume cover crop, corn, wheat, and soybean. After 128 years, the practice of rotating cotton with corn and winter legumes has significantly enhanced the chemical, physical, and biological properties of the soil, particularly in the top 15 cm, thereby improving overall soil health. Notably, continuous cotton rotations incorporating a winter legume cover crop contain 2.5 times more soil organic matter and yield over 3 times more cotton lint than continuous cotton without any winter legume cover crop, and this is achieved without the use of supplemental nitrogen fertilizer. This finding underscores the substantial benefits that winter legume cover crops offer in enhancing crop productivity and promoting agricultural sustainability.

#### CENTURY-LONG COVER CROP, ROTATION AND FERTILITY MANAGEMENT PRACTICES ON SOIL HEALTH AND ORGANIC MATTER COMPOSITION IN A SUBTROPICAL COTTON FIELD OF USA

J. WANG<sup>1</sup>, Y. TIAN<sup>1</sup>, A. AHMED<sup>1</sup>, M.A. HAIDER<sup>1</sup>, B. ZHOU<sup>1</sup>, C.C. MITCHELL<sup>2</sup>

<sup>1</sup> School of Plant, Environmental and Soil Sciences, Louisiana State University, Baton Rouge, USA

<sup>2</sup> Crop, Soil and Environmental Sciences Dept, Auburn University, Auburn, USA

Organic matter dynamic plays a major role in maintaining soil health for sustainable crop production and is influenced by functional molecular diversity interplay with spatial and temporal variations. In this study, we explore long-term effects of crop rotation, winter legume cover crop and nitrogen (N) fertilization on soil organic carbon (SOC) molecular fractions, aggregate stability as well as enzyme activities that control nutrient cycling by characterizing soils of the world's oldest (> 120 years) continuous cotton experiment. Field treatments include: 1) Continuous cotton with no winter legume/no inorganic N fertilizer, 2) Continuous cotton with winter legume, 3) Corn-cotton rotation with winter legume, 4) Corn-cotton rotation with winter legume plus inorganic N fertilizer, and 5) Continuous cotton with inorganic N fertilizer. Total organic C (TOC), total N (TN) as well as acid-hydrolysis C (AHC) and water extractable organic C of bulk soil and different aggregate fractions along with SOC composition were characterized. Corn-cotton rotation with winter legumes significantly increased bulk soil TOC, AHC and TN as well as aggregates-associated C over other treatments. Corn-cotton rotation with winter legumes increased macroaggregates by over 90%, whereas continuous cotton with winter legumes or inorganic N fertilizer had less than 7% increase compared to control plots. Soil samples of corn-cotton rotation with winter legumes or winter legumes plus inorganic N fertilizer had more diversified compounds of polysaccharides, aliphatic, aromatic, lignin, and phenols than continuous cotton with winter legumes or inorganic N fertilizer. Corn-cotton rotation also showed higher activities of glucosidase, glucosaminidase, phosphatase and arylsulfatase than continuous cotton without corn rotation regardless winter legume inclusion or inorganic N fertilization. Aggregate mean weighted diameter and geometric mean diameter were positively related to TOC, N-containing compounds, phenols as well as polysaccharides and aliphatics. Synergistic interactions induced by diversified inputs of SOM compositions between corn rotation and winter legumes were responsible for observed SOC accumulations, aggregate stability as well as enhanced enzyme activities in these subtropical cotton fields.

#### LEVERAGING 135 YEARS OF CONTINUOUS RESEARCH AT SANBORN FIELD TO UNDERSTAND SOIL HEALTH

T. REINBOTT<sup>1</sup>, K. VEUM<sup>2</sup>, R. KREMER<sup>1</sup>, W. WALTER<sup>1</sup>

<sup>1</sup> University of Missouri, Columbia, USA

<sup>2</sup> USDA-ARS, Columbia, USA

Sanborn Field, established in 1888, is the 3rd oldest continuous research site in world. The 40 experimental plots focus on crop rotation, crop species, and fertility inputs. Approximately every 25 years beginning in 1915, four 1.2 m soil cores are taken from each plot and divided into fixed, 10 cm increments. Historically, sample analysis focused on basic soil fertility measurements. In 2020, an additional four cores were taken from each plot and divided into soil horizons and analyzed for soil health indicators. In grain production systems, monoculture wheat (*Triticum aestivum*) had higher soil health indicators regardless of fertilizer or manure compared to monoculture corn (*Zea mays*) or soybean (*Glycine max*) and were similar to crop rotation within fertility treatment. For example, water stable aggregate stability (WSA) was 328 mg g<sup>-1</sup> for continuous wheat with manure, 333 mg g<sup>-1</sup> for continuous wheat no fertilizer inputs, compared to 270 mg g<sup>-1</sup> for continuous corn with manure, and only 110 mg g<sup>-1</sup> for continuous corn with no fertilizer inputs. In addition, WSA was 395 mg g<sup>-1</sup> in a corn-wheat-red clover (*Trifolium pratense*) rotation with manure versus 220 mg g<sup>-1</sup> with commercial fertilizer. However, WSA values were reduced to 230 mg g<sup>-1</sup> when soybean replaced red clover in the rotation with manure and was unchanged in the commercial fertilizer treatment. Soil health indicators were analyzed using the Soil Health Assessment Protocol and Evaluation (SHAPE) method to evaluate which soil health indicators were the most limiting. It was found that higher soil health scores under wheat can be attributed to greater microbial activity rather than to greater TOC and AC whereas, manure was important to improving soil health as a source of TOC and AC. Surprisingly, even in perennial systems soil health at Sanborn Field is limited by TOC and AC. Results illustrate the value of long-term research in guiding current management decisions affecting sustainable cropping systems while maintaining optimum soil health.

**THE 100-YEAR-OLD FIELD EXPERIMENTS OF THE INSTITUTE OF AGRICULTURE, WARSAW UNIVERSITY OF LIFE SCIENCES – SGGW, SKIERNIEWICE, CENTRAL POLAND: HISTORY, RECENT RESEARCH AND FUTURE PERSPECTIVES**

L. UZAROWICZ, W. STEPIEN, D. GOZDOWSKI, E. HEWELKE, J. JONCZAK, T. NIEDZINSKI, A. PERZANOWSKA, A. PEDZIWIATR, B. RUTKOWSKA, Z. ZAGORSKI

Warsaw University of Life Sciences - SGGW, Warsaw, POLAND

Long-term agricultural field experiments of the Institute of Agriculture, Warsaw University of Life Sciences – SGGW, are located in Skierniewice, central Poland. The long-term fertilization experiments in Skierniewice were established in 1921 on Luvisols. These experiments are the oldest existing experiments in Poland, 5th in Europe and 7th in the world. The experiments have been carried out on an area of 4.8 ha where 670 plots are located. The experiments have been carried out in various fertilization combinations (Ca, CaNPK, NPK, CaPK, CaPN, CaNK, PK, PN, KN, farmyard manure) including control plots with no fertilization. Different fertilizer types are used in the experiments. The four crop rotation are applied: 1) 5-field crop rotation, 2) rotation without manure and legumes, 3) rotation without manure with legumes and 4) three long-term monocultures (rye, potatoes and triticale). Long-term agricultural field experiments of the Institute of Agriculture, Warsaw University of Life Sciences – SGGW, have been the subject of many studies in the area of agricultural sciences, soil sciences, environmental sciences, biological sciences and food sciences. In recent years, long-term agricultural experiences have become increasingly important due to the possibility of observing long-term trends in changes of soil properties and yields depending on long-term agricultural practices and weather/climatic conditions. Observations of long-term trends may, in turn, be the basis for creating forecasts of changes in crop yields and the rate of sequestration/loss of organic carbon in the soil in the context of climate change. Forecasts can be used by decision-makers at the national and international level to develop agricultural development strategies and introduce good practices to reduce the impact of agriculture on the environment, including the climate.

Some research was financed by EJP SOIL program, NCBR project EJPSOIL/I/78/SOMPACS/2022 and through the partners of the Joint Call of the Cofund ERA-Nets SusCrop (Grant N° 771134), FACCE ERA-GAS (Grant N° 696356), ICT-AGRI-FOOD (Grant N° 862665) and SusAn (Grant N° 696231) under the 'ConnectFarms' project.

<sup>2</sup> Helmholtz Centre for Environmental Research - UFZ, Department of Community Ecology, Halle, GERMANY

<sup>3</sup> Helmholtz Centre for Environmental Research - UFZ, Department of Soil Ecology, Halle, GERMANY

The Research Station in Bad Lauchstädt operates a variety of long-term field experiments with different treatments and scientific foci. The oldest experiment is the Static Fertilization Experiment, which was established already in 1902. It is 4 ha in size and consists of 8 field stripes supplied with different amounts of organic and mineral fertilizers. The soil is a highly productive Chernozem and its topsoil properties and plant parameters are continuously monitored. The experiment has survived wars and political upheavals. While the crop rotations changed for the first time in 2014, the fertilization regime has not and, above all, the agricultural management is documented in detail for all experimental plots. With that, this experiment is a highly valuable treasure of data, especially for a better understanding of soil processes and their interactions. This understanding feeds into mechanistic simulation models. They are essential tools to actually predict the impact of changing boundary conditions, brought about by changes in climate, land use and agricultural management practices, on multiple soil functions. In this presentation, we will demonstrate how this long-term field experiment helped to develop and validate the systemic soil model BODIUM. We further show how the integration of modelling and long-term monitoring of soil and plant variables can increase the impact of long-term experiments in the future.

#### CROP AVAILABILITY OF SOIL PHOSPHORUS IN SWEDISH LONG-TERM SOIL FERTILITY EXPERIMENTS

S. BRAUN <sup>1</sup>, T. MCLAREN <sup>2</sup>, A. OBERSON DRÄYER <sup>3</sup>, J. ..P. GUSTAFSSON <sup>1</sup>

<sup>1</sup> The Swedish University of Agriculture, Department of Soil and Environment, Uppsala, SWEDEN

<sup>2</sup> The University of Queensland, School of Agriculture and Food Sustainability, Queensland, AUSTRALIA

<sup>3</sup> ETH Zurich, Institute of Agricultural Sciences, Lindau, SWITZERLAND

The Swedish university of Agricultural Sciences (SLU) has a long tradition of agricultural field experiments, going back to early 20th century. Currently there are 61 active long-term experiments (LTE) at SLU covering: plant nutrition, crop production systems, landscape ecology, water quality management, agricultural water management, soil tillage, and weed biology and weed control. One of the unique features of the Swedish LTES are the geographical gradient, with experimental sites spanning from Piteå in the north to Trelleborg in the South. The Swedish LTE infrastructure includes an extensive database and a physical sample archive.

One important experimental series is the Swedish long-term soil fertility experiments, consisting of nine separate sites established between 1957 and 1966. These experiments have a complex design, and one of the experimental factors is the level of phosphorus (P) fertilizer addition. By using historical yield and soil data and archived samples from six sites, we studied how the P budget (P input– P removed by harvest) related to grain crop yields, chemically extractable soil P, and isotopically exchangeable soil P. We found that when P fertilizer was omitted average crop yields were 55-97 % of maximal yield, but the yield levels did not decline during >50 years at five out of six sites, showing that the soils had a large ability to mobilize P for crop uptake. At most sites there was no increase in average grain yield when more P than what was removed by harvest was added. Both extractable and exchangeable P were strongly correlated to the P budget. About half of the added excess P could not be accounted for in an increase in total P in the top 0-20 cm soil. The results indicates that the majority of the added excess P that stayed in the top soil has been retained in plant available forms. However, when the P budget was close to zero, both Olsen-P and oxalate-P decreased over time.

<sup>3</sup> Payakumbuh Agriculture Polytechnic Institute, Payakumbuh, INDONESIA

<sup>4</sup> The University of Sydney, Sydney, AUSTRALIA

Indonesia is well-known as one of the most active volcanic regions . Volcanic soils cover an area of 31.7 million ha, are considered as the most productive soils, high agronomical value and a high human carrying capacity. Soils in Java known for their high productivity are mostly developed from volcanic products. Nevertheless not all volcanic soils are the same, it can range from acidic-infertile soils derived from Rhyolitic parent materials to andesitic to dacitic volcanic materials. Here we show the geochemical properties of various volcanic materials and how they developed into various types of soils. For example, in Kerinci,, after 100 years of tea cultivation the soils are friable with low BD, SOM is still high, have high P-retention (>90%). Soil weathering controls P-retention, with an increasing P-retention as the soils weathered. We further identify research gaps in soil C storage, microbial interactions, and volcanic ash management.

Despite the renowned high OC content, resilience of volcanic soils, current soil management practices have led to a significant reduction in their carbon content. This ongoing depletion presents a concerning trend, and addressing the repercussions of this depletion is a critical knowledge gap. It is imperative to evaluate the susceptibility of volcanic soils in Indonesia to the impacts of climate change and formulate strategies to bolster their resilience. Further research into the intricate interplay between microbial communities is needed, regarding their contributions to fertility, nutrient and carbon cycling, and plant productivity, offering valuable insights for agriculture and land management.

To bridge the gaps, collaborative interdisciplinary research is imperative. Continuous monitoring and data collection are essential to comprehending the dynamic nature of volcanic soils and their responses to evolving environmental conditions. Researchers and institutions in Indonesia, in collaboration with international partners, have a pivotal role in advancing our understanding of volcanic soils and securing them. The study of volcanic soils and soil science in Indonesia aligns with and contribute significantly to achieving multiple

Soil microbes are a key component of soil biodiversity and play an essential role in soil ecosystem services including nutrient cycling. Their presence and abundance are used as indicators to assess soil biodiversity and soil health status. Over the last several years, different parameters have been developed to monitor soil microbes, but the lack of harmonized protocols makes comparison of results among laboratories across the world challenging.

The FAO's Global Soil Laboratory Network (GLOSOLAN) has developed a bottom-up, inclusive approach to harmonize and publish standard operating procedures (SOPs) that actively involves all its members. Globally harmonized SOPs greatly enhance global cooperation and comparability of data.

According to the Global Soil Laboratory Assessment 2020, only about 44 percent of soil laboratories worldwide have the capacity and equipment needed to measure soil biological parameters. A joint working group on soil biological analysis established between GLOSOLAN and the FAO's International Network on Soil Biodiversity (NETSOB), has organized activities to build the capacity of soil laboratories worldwide to measure soil biological parameters. Moreover, globally harmonized SOPs have been published for the determination of soil respiration rate, microbial biomass, and enzyme activities. Other protocols on micro-, meso- and mega-fauna are under development as well and will be added to the other 25 SOPs already published by GLOSOLAN on soil chemical and physical parameters, which are open access in various languages.

Such SOPs are being adopted as new standards to harmonize soil data globally. When possible, GLOSOLAN encourages national governments to support soil laboratories to combine bottom-up and top-down activities for the development and adoption of globally harmonized SOPs.

#### ADVANCING SOIL HEALTH ON GRAZED PASTORAL FARMS – A NEW ZEALAND PERSPECTIVE

N. SCHON<sup>1</sup>, A. MACKAY<sup>2</sup>

<sup>1</sup> AgResearch, Christchurch, NEW ZEALAND

<sup>2</sup> AgResearch, Palmerston North, NEW ZEALAND

Pastoral farms rely on soils for the provision and regulation of a wide range of ecosystem services that benefit the farm and its surrounding environments. Maintaining services such as primary production and water purification and regulation is dependent on the chemical, physical, biological and organic condition or health of the soil. Despite global interest in advancing the measurement and management of soil health, there is currently no universal assessment available for growers to use.

On-farm assessments of soil condition in New Zealand are largely limited to fertility, to inform nutrient management plans. Additional assessments of soil organic matter, physical condition and biological activity provides a more complete picture of the overall health of a soil and its ability to provide ecosystem services. We detail a method that extends current soil fertility monitoring to include such additional indicators of soil health. Selected indicators have target ranges identified for optimal performance and are known to be influenced by management decisions.

This soil health assessment approach is currently being evaluated in a study conducted on dairy farms across multiple soil types and climates in New Zealand. Annual assessments of soil health have been conducted on the major land management units on each farm. Differences in soil health were observed across soil types. There were some changes across three years, with specific events having the ability to degrade soils quickly, while the recovery of some indicators has been slow. Overall, soils across the farms tended to be in good health, with only a few indicators outside the target range.

Extending soil assessment from fertility to a broader consideration of soil health enriches the knowledge of growers, with the potential for improved decision making on-farm. Better linkages between the health of the soil and its ability to provide ecosystem services are still required to ensure the total value of healthy soils is recognized in the context of the farm and its surrounding environments.

#### SOIL HEALTH - POLICY INTERFACE IN THE CONTEXT OF THE EU AND NATIONAL STRATEGIES

J. SOBOCKÁ

National Agricultural and Food Centre, Soil Science and Conservation Research Institute, Bratislava, SLOVAK REPUBLIC

Opportunities to include soil health in the EU policies and strategies are highlighted in Green Deal which aims to transform the EU into a modern, efficient, and competitive economy. Soil Strategy to 2030, Directive on Soil Monitoring and Resilience, the European Soil Observatory and Soil Mission Board EU are listed recently which is very good message mainly for soil scientists. The question is: how to convince stakeholders, including farmers, policy makers, agricultural investors etc. to implement measures addressing future threats? A solution provides Soil Mission Board EU. It recommends development of a National Hub builds upon the existing stakeholder participation with structure best suited to each specific country. The National Hubs composed of a broad range of different stakeholders, all include at least policy makers and scientists, etc. and represent a significant instrument for stakeholders' engagement. National Hubs will no longer have a formal role but could develop into Soil Mirror Groups. Which is expected to contribute to raising stakeholder awareness (soil literacy) and know-how about the importance of conserving and improving soil health for different land use contexts, such as agriculture, forestry, (post-)industrial and cities. Ideally, the Mirror Group is composed of two sub-groups: 1) Policy Group: composed of representatives of entities under the sectoral Ministries with alignment with the Mission (Agriculture, Environment, Science, et al) + Soil Mission Board member. Stakeholder Group includes sectoral organizations, researchers, and representatives of key groups in civil society, as well as representatives of Soil Mission Living Labs and existing Communities of Practice. Some common success criteria for active and functional National Hub members in the EJP SOIL were identified. Many questions are needed to response: What do we know about people managing soil? How do they make decisions? How to implement new business models? Which type of regulations are needed? How R&I should be linked to practice via living labs?

#### USING COMBUSTION ANALYSIS TO SIMULTANEOUSLY MEASURE SOIL ORGANIC AND INORGANIC CARBON FOR SOIL SURVEY

T. CARTER<sup>1</sup>, C. SCHAECHER<sup>2</sup>, S. MONTEITH<sup>2</sup>, R. FERGUSON<sup>2</sup>

<sup>1</sup> USDA-NRCS, Soil Science Research Branch, National Soil Survey Center, Lincoln, USA

<sup>2</sup> USDA-NRCS, Kellogg Soil Survey Laboratory, National Soil Survey Center, Lincoln, USA

Soil organic carbon (SOC) and soil inorganic carbon (SIC) are of longstanding interest due to their relationship with other key soil properties and indications for soil health and carbon storage. At the USDA-NRCS Kellogg Soil Survey Laboratory (KSSL), total carbon is determined via dry combustion analysis, while calcium carbonate (CaCO<sub>3</sub>) equivalent is determined via manocalcimetry. For calcareous (carbonate bearing) samples, SIC is estimated as 12% of CaCO<sub>3</sub> equivalent, while SOC is estimated as the difference between measured total carbon and estimated inorganic carbon. An alternative dry combustion method for the measurement of SOC and SIC pools was evaluated with the goal of directly measuring – not estimating – SOC and SIC. The alternative dry combustion method comprises two variants that differ in temperature-ramps and carrier gases used. Both variants were applied in duplicate to 110 diverse samples, including 32 calcareous samples, from across the USA that had been previously characterized by the KSSL. Samples were selected to capture wide variability in carbon contents. Comparing carbon data outcomes with legacy KSSL characterization data revealed one method variant as best for calcareous samples, whereas the other variant was preferred for non-calcareous samples. A combination of the two method variants offers an accurate and direct measurement of SOC and SIC. For calcareous samples, mid-infrared spectral analysis demonstrated the alternative method as slightly more accurate than legacy KSSL methods for estimating SOC and SIC.

The long-term analysis of spatial and temporal patterns of crop yields provides insights on how yields vary in a field, with parts of field constantly producing either high yields or low yields and other parts that fluctuate from one year to the next. The concept of yield stability has shown to be informative on how plants translate the effects of environmental conditions (e.g., soil, climate, topography) across the field and over the years in the final yield, and as a valuable layer in developing prescription maps of variable fertilizer rate inputs. Using known relationships between soil health and crop yields, we hypothesize that areas with measured constantly low yield will return low carbon to the soil affecting its health. On this premise, yield stability zones (YSZ) provide an effective and practical integrative measure of the small-scale variability of soil health on a field relative basis. We tested this hypothesis by measuring various metrics of soil health from commercial farmers' fields in the north central Midwest of the USA in samples replicated across YSZ, using a soil test suite commonly used by producers and stakeholders active in agricultural carbon credits markets. We found that the use of YSZ allowed us to successfully partition field-relative soil organic carbon (SOC) and soil health metrics into statistically distinct regions. Low and stable (LS) yield zones were statistically lower in normalized SOC when compared to high and stable (HS) and unstable (US) yield zones. The drivers of the yield differences within a field are a series of factors ranging from climate, topography and soil.

#### EXPLORING THE AGGREGATE - ORGANIC MATTER - MICROBIAL COMMUNITY CONTINUUM FOR CHARACTERIZING SOIL HEALTH CHANGES UNDER HUMAN DISTURBANCE:

G. PAN<sup>1</sup>, Z. ZHAO<sup>1</sup>, C. LIU<sup>1</sup>, S. CHEN<sup>2</sup>, J. TIAN<sup>1</sup>

<sup>1</sup> Dept. Soil Science, Nanjing Agricultural University, Nanjing, CHINA

<sup>2</sup> College of Environment and Resources, Yangzhou University, NANJING, CHINA

Soil health should be envisaged with characterizing soil organic carbon (SOC) preservation, microbial biomass/activity and biochemical performance in a soil continuum context. A soil landscape sequence of forest land on hills, orchards and drylands in slope lands and paddy fields in the basin was established and undisturbed topsoil cores randomly sampled for each soil-landscape, in a hilly rural area. Water-stable aggregate size fractions (macroaggregate, microaggregates and silt-clay) were separated. Dissolvable OC (DOC), microbial biomass OC(MBC), phosphorus lipid fatty acids (PLFAs) contents and extracellular enzyme activities as well as biomarker molecular abundance analyzed for all topsoil samples across the landscapes sequence. There was a sharp decline in topsoil SOC in cultivated soil-landscapes with a great reduction of macroaggregates mass proportion and significant increase in the microbial abundance and DOC portion to SOC. Parallely, diversity of PLFA groups and functional diversity with EEAs were lower in cultivated lands compared to conserved forest. Meanwhile, abundances of biomarker molecules were all higher in forest than in drylands and paddy, with a higher ratio of plant derived lipids to microbial derived lipids. While the relative abundance of bound lipids and of stable lignin was well correlated, the relative abundance of labile OC was closely correlated to total SOC across the landscapes. Moreover, X-ray CT tomography of macroaggregates revealed that total porosity and connected porosity was both indicative of OC decline (POC in particular) in aggregate fractions, in line with the mass proportion change. Thus, soil health was greatly impacted by cultivation, mimicked with the changes in OC level, pool distribution and molecular composition in combination of microbial abundance, diversity and biochemical activity, across the SOM-Aggregates-Microbes-Enzymes continuum. Overall, the ratio of DOC/SOC, DOC/MBC and abundance ratio of G+/GC and of PLFAs/SOC could trace microbial shift from K strategy to R strategy while the ratio of POM/MAOM and abundance ratio of plant lipid to microbial lipids are those for SOM protection and selected preservation in the soils.

#### CHALLENGES AND OPPORTUNITIES TO IMPROVE SOIL MONITORING SYSTEMS: THE CASE OF THE EMILIA-ROMAGNA REGION IN ITALY

P. TAROCCO <sup>1</sup>, A. APREA <sup>1</sup>, E. MEDINA-ROLDAN <sup>2</sup>, R. LORENZETTI <sup>2</sup>, F. UNGARO <sup>2</sup>

<sup>1</sup> Regione Emilia-Romagna, Area Geologia Suoli e Sismica, Bologna, ITALY

<sup>2</sup> Consiglio Nazionale delle Ricerche, Istituto per la BioEconomia, Sesto F.no, ITALY

The new proposed Directive of the European Parliament and of the Council on Soil Monitoring and Resilience (also called “Soil Monitoring Law”, SML) positions soil health as a key concept to increase the resilience of European soil systems and their capacity to mitigate climate change. The directive is a fundamental step to guide concrete actions and criteria to reach targets related to the extent and containment of soil degradation, it sets targets to restore degraded soils; as well as the indicators to be monitored to do so. The SML opens up an important discussion forum from the pedological technical point of view, mainly regarding indicators and thresholds to be used to monitor soil health status in face of the great pedo-climatic diversity of the different EU member states. In Italy, despite the absence of an institutional soil monitoring network at national scale, soil monitoring activities are carried out by regional soil services, mainly in the frame of regional funded projects (e.g. rural development programme RDP). In this context, the Emilia-Romagna (ER) region in northern Italy, has built, maintains and integrates along the time a rich-data soil information system thanks to multi-institutional efforts. The ER soil information system offers public access, thematic high-resolution maps on several soil properties and soil-based ecosystem services to support stakeholders on environmental decision-making and monitoring of soil health status with respect to regional land use and management. Some of these experiences are at odds with some of the SML prescriptions. These discrepancies are related mainly to those indicators and their thresholds applicable at the EU level, where many of the prescribed thresholds are considered rather harsh given the ER regional conditions and experience. On the other hand, the SML also opens up great opportunities for the expansion of current soil monitoring efforts, mainly in relation to those indicators where the member states can decide on thresholds criteria such as heavy metals and persistent organic pollutants concentrations.

<sup>4</sup> Rothamsted Research, Sustainable Soils and Crops, Harpenden, UNITED KINGDOM

Soils play a vital role across many sectors, particularly agriculture and forestry. With the need to feed a growing population, maintaining healthy soil to ensure the production of food and fiber becomes essential. There is still an ongoing debate about the use of the terms “soil quality” versus “soil health”, despite the need for a clear definition for soil assessment purposes. Soil quality has been primarily used by scientists since the 1970s, developing from an agricultural productivity-focused definition to including the importance of soils to sustain biological productivity, to maintain environmental quality, and to promote animal and plant health. Starting in the 1990s, criticism developed regarding the focus of these definitions on the use aspect of soils for humans. Consequently, increasing attention, especially by non-scientist stakeholders like farmers, was given to the concept of soil health, including the capacity of soil, defined as a finite non-renewable resource, to function as a vital living system. This definition emphasizes a more holistic understanding of soils and its biological processes, rather than the provision of services exclusively for human benefit. Our research aims to investigate these concepts and related aspects like indices, by using the methods of literature review and meta-analysis. Our preliminary results and synthesis of literature will be presented.

<sup>2</sup> CIRAD UMR ABSys, Bangkok, THAILAND

The recent European directive, the Soil Monitoring Law, defines soil health as the capacity of soil to function and provide ecosystem services. However, this functionalist view of soil health does not align with current literature. Most studies and databases on soil health focus mainly on stock indicators such as C, N and microbial biomass, while indicators of soil functions are rarely included. To address these methodological limitations, a new field method has been developed to assess soil functions. Biofunctool® is a method that addresses the multifunctionality of soil. It takes into account the relationship between physico-chemical and biological properties. It includes nine low-cost field indicators that allow the assessment of three main soil functions: carbon dynamics, nutrient cycling, and maintenance of soil structure. Biofunctool® is particularly useful for assessing the impact of agricultural practices on soil health. The Biofunctool® methodology has been applied in a variety of soil contexts, including tropical soils in Asia and Africa, and in different agronomic situations, such as conservation agriculture, agroforestry and tree plantations. This study aims to present a synthesis of Biofunctool® applications to highlight their relevance for the evaluation of agroecological practices. The study combines the results of six published articles and ongoing projects that use the Biofunctool® methodology. Biofunctool® has been shown to improve our understanding of the impact of agricultural practices on soil functions and could serve as a basis for integrating soil health into broader environmental analyses. However, we will also discuss the current main limitations of the method and suggest different perspectives for improving the method and facilitating its wider dissemination.

#### PROPOSING A FLEXIBLE ASSESSMENT FRAMEWORK TO ADDRESS SOIL HEALTH GAPS IN THE GLOBAL SOUTH

G. BONGIORNO<sup>1</sup>, A. VISSCHER<sup>1</sup>, M. PULLEMAN<sup>1,2</sup>

<sup>1</sup> Wageningen University & Research, Soil Biology group, Wageningen, THE NETHERLANDS

<sup>2</sup> International Centre for Tropical Agriculture, Cali, COLOMBIA

Soil health is the capacity of soils to perform multiple ecological functions, impacting broader societal benefits connected to sustainable development goals (SDGs). Smallholder farmers in the Global South are particularly vulnerable to soil degradation resulting from unsustainable agricultural management, exacerbated impacts of climate change and threatening food security and rural livelihoods. Tackling these interlinked global challenges requires a focus on restoration of soil health. The popularity of the soil health concept has led to an overwhelming demand for indicators, methods and technologies that can be used to assess soil health in robust and cost-effective ways, while obtaining evidence of the links between agricultural practices, soil health and agronomic, environmental and social benefits.

We discuss progresses and challenges for the development of soil health assessment frameworks and their application in the diverse contexts of smallholder farmers in the Global South. Based on literature review and experiences working across cropping systems in Africa and Latin America, we propose a flexible soil health framework adaptable to various systems, contexts and end users. We also identify research gaps that need to be addressed to strengthen its application and impact.

We conclude that (i) there are still challenges associated with the measurement and interpretation of the multiple dimensions of soil health, especially for biological indicators, 2) empirical studies linking soil health to agronomic and environmental outcomes, including trade-offs, are scarce, especially in the context of smallholders in developing countries; 3) the use of practical and low cost soil health indicators to support farmer decision making has received little attention. This flexible soil health assessment framework can help end-users gain insight into the baseline status of their soil, contextualize soil health, monitor changes, reveal and optimize trade-offs and synergies that affect the sustainability of the agronomic interventions and inform interventions. Ways to overcome knowledge or information gaps are discussed focusing on approaches that offer promise to create positive impact for smallholder farmers in the Global South.

#### SITE-SPECIFIC BENCHMARKS OF INDICATORS FOR A TAILORED SOIL HEALTH ASSESSMENT IN DENMARK

S. GUTIERREZ, L. GOMES, A. MØLLER, A. BEUCHER, L. WOLLESEN, M. GREVE

Department of Agroecology, Soil Physics and Hydropedology, Aarhus University, 8830, Tjele, DENMARK

Successfully achieving the goal of promoting healthy soils requires gathering data, information, and knowledge, particularly due to the significant diversity in soil types, climatic conditions, and land uses. We used a set of indicators and a site-specific benchmarking approach for evaluating soil health in arable lands from Denmark.

We compiled national datasets detailing topsoil organic carbon (OC), bulk density, soil pH, electrical conductivity, clay-to-OC ratio, and two model-informed properties such as water erosion, and nitrate leaching. To define units with similar conditions and account for variations in these soil health indicators, we categorized Danish soils into different strata using textural classes, landscape elements, and wetland types. We computed benchmarks for the indicators by analyzing data from each stratum. Our approach provided point-based results that allowed us to analyze the status of every single indicator, but also provided a spatially explicit overview of soil health, allowing the integrative analysis of the indicators by interpreting the occurrence of atypical areas in various indicators. We implied that the use of organic sources for fertilization would improve the soil health status relative to average conditions from the benchmarks; however, specific sources must be cautiously managed as improper application can lead to overfertilization, severely impacting soil and water quality.

We offered a concept for setting practical targets tailored to specific farming environments. The insights garnered from this study may be a basis for establishing a soil monitoring network for Denmark, in compliance with the Soil Monitoring Law that aims to achieve healthy soils across Europe by 2050. This approach avoids reliance on generic thresholds, ensuring a more unbiased assessment.

#### PUZZLE PIECES OF SOIL HEALTH THROUGH SOIL ANALYSES

J.A.C. REIJNEVELD<sup>1</sup>, O. OENEMA<sup>2</sup>

<sup>1</sup> Eurofins Knowledge Center, Wageningen, THE NETHERLANDS

<sup>2</sup> Wageningen University & Research, Wageningen, THE NETHERLANDS

Soil health encompasses soil physical, chemical, and biological characteristics. Commonly, many different tests are needed for a full soil health assessment, which is laborious, expensive, and many tests have a high environmental footprint. New broad-spectrum soil tests offer the potential to assess many soil characteristics quickly, but often face challenges with calibration and validation. Here we describe the results of an extensive research program which aimed at overcoming the aforementioned challenges. Two broad-spectrum techniques were selected, i.e., Near Infra-Red Spectroscopy (NIRS) and 0.01 M CaCl<sub>2</sub> extractions of soil (1:10 soil:solution ratio) followed by discrete analysis and ICP-MS of the extractant for assessing plant available nutrients. NIRS was extensively calibrated and validated for various countries in Europe, as well as for various regions in China, New Zealand and Vietnam. Since its step-wise implementation in 2004, more than 3 million soil tests have been conducted. The results of the research program indicate that the accuracy of NIRS determinations for a wide range of soil physical, chemical and biological indices is high ( $R^2 > 0.90$ ). The multi-constituent soil analysis (through NIRS) are used in the Soil Carbon Check (SCC), a rapid tool to measure and monitor C(O<sub>2</sub>) sequestration (SDG13) in farmers' fields. To get insight in the bio-availability of nutrients and (heavy) metals, 0.01 M CaCl<sub>2</sub> is used for 15 essential and beneficial nutrients and for 9 (heavy) metals. The two broad-spectrum soil tests combined have been calibrated and validated now for more than 35 soil characteristics (puzzle pieces). These soil characteristics (including Clay/SOC ratio, available phosphorus, sodicity and salinity indices, pH-water/CaCl<sub>2</sub>, bio available heavy metals and biological indices) were incorporated in Soil Health Indicator, which is accompanied by a comprehensive soil health report for users (farmers, advisors, research, retail and government). The approach allowed us to routinely introduce the soil nutrient intensity-buffering-quantity concept into agricultural practice and to provide guidance to attain healthier soils, and thereby contribute to achieving the SDSs.

Soil health has become a key topic for governments, stakeholders, and scientists following the proposal of a soil monitoring law by the EU aimed at protecting and restoring soils. Soil health is commonly associated with soil quality for crops, but is essentially a very different concept and is equally important concept for grasslands, forests and wetlands. Various soil health indicators, such as chemical, physical, and biological indicators, are utilized to assess the health of soils. However, knowledge of these indicators for specific soils, topographies, and land use and land cover (LULC) is limited. Not all indicators can be universally applied to all LULC types. Therefore, it is essential to first understand the area and then utilize appropriate information to define soil health accurately.

We propose a new soil health framework called SHERPA (Soil Health Evaluation, Rating Protocol, and Assessment), which considers a soil healthy if its natural functions are not reduced or disturbed by humans. This framework is divided into two parts. Part 1 provides thresholds and criteria to identify human-induced soil degradation processes, such as soil erosion, landslides, drainage, heavy metal contamination, nitrogen surplus, and phosphorus deficiency. Part 2 offers scientific criteria for different indicators (e.g., geology, climate, organic layer composition, and soil structure information) to assign a soil health index for various LULC types. We have defined scientific criteria and a rating protocol for the LULC types grasslands, arable lands, orchards, and vineyards, forests and wetlands. The goal of SHERPA is to develop a soil health index map at the European scale within the R environment.

The precise determination of soil organic carbon (SOC) and soil inorganic carbon (SIC) content in calcareous soils is still open to debate. One way to quantify the SOC and SIC pools in a soil sample is to remove one or the other pool via pre-treatment and then calculate total carbon (TC) as the sum of SOC+SIC. Another option is to determine total carbon (TC) and SIC (or SOC) content separately and then calculate the SOC (or SIC) content, by difference. Both approaches have drawbacks. This study examined the effect of pre-treatment on carbon content measurements. Altogether, 71 surface and sub-surface soil samples were collected in Germany, Hungary and France. HCl decarbonation and ignition was applied to eliminate SIC or SOC, respectively.

In general, the TC content of bulk samples was lower than the sum of SIC+SOC content ( $R^2=0.952$ ): in samples with less than 6% TC content, the sum of SIC+SOC either over- or under-estimated TC but in samples with more than 6% TC content, the sum of SIC+SOC consistently overestimated TC. This suggests that pre-treatment resulted in incomplete carbon removal.

Measured values of the  $\delta^{13}C$  of SIC were usually higher than  $-14\text{‰}$ , although several samples with SIC contents below 1% were depleted in  $\delta^{13}C$  (as low as  $-31\text{‰}$ ), indicating the presence of SOC in these samples. This suggests that SOC is not completely eliminated by ignition. This conclusion is supported by the fact that calculated values of the  $\delta^{13}C$  of TC (using weighted averages of the  $\delta^{13}C$  of individually measured SIC and SOC pools) were more negative than measurements of the  $\delta^{13}C$  of TC obtained from direct analysis of bulk soil.

This research was funded by the SIC-SOC-DYN “Organic and inorganic carbon dynamic in calcareous soils” project of the 1st external Call within the EJP SOIL program, the National Research, Development and Innovation Fund, Hungary [Project N° 2019-2.14-ERA-NET-2022-00037 and FK 142936] and the French National Research Agency [Project N° ANR-22-SOIL-0003-01].

<sup>4</sup> University of Palermo, Palermo, ITALY

Soil survey at large scale for monitoring soil health at high space-time resolution is on top of the political agenda, and it has recently gained importance for EU R&I and many other stakeholders. Sampling strategies based on selections of legacy and new locations can be efficient and best capture the soil (physicochemical and biological) spatial variability.

Traditionally, the definition of new sample locations has been based on randomized and stratified sampling designs and is sometimes supported by geostatistics optimization, mainly by studying the spatial dependence in vast regions with rugged terrain and the ease of reaching a specific area. However, contemporary digital soil mapping mostly relies on environmental data (digital elevation models, gridded climate data such as mean annual temperature and precipitations and their derivatives), upon which machine learning (ML) models predict soil properties.

In this work, a simulation explored the impact of various sample strategies and densities using legacy soil knowledge to allocate samples. The case study is built upon a legacy dataset of soil pedological profiles and digital soil maps where soils are classified according to the WRB system. The main scenarios evaluated are an equally spaced grid versus stratified sampling, depending on environmental variability and legacy data availability. Soil types were aggregated to define pedo-landscapes, and similarities were analysed statistically. In contrast, locations of legacy point data were considered as possible priority locations for allocating new monitoring sampling points.

Measurement errors were assessed across multiple sampling designs and scored according to the pedo-landscape and soil properties. Our findings will indicate the optimal density of samples per pedo-landscape.

<sup>3</sup> Universidade Tecnológica Federal do Paraná, Santa Helena, BRAZIL

In alignment with global health concerns of agricultural soils, since July 2020, Brazil has adopted the Soil Bioanalysis (SoilBio) approach, a groundbreaking initiative that integrates two key soil enzymes – arylsulfatase (ARYL) and beta-glucosidase (GLU) – into routine soil testing.

This approach has allowed soil health (SH) monitoring at the farm scale by combining chemical and biological indicators within a Soil Quality Index (SQI) framework, which includes three soil functions: (F1) nutrient cycling (based on ARYL and GLU activities), (F2) nutrient storage (based on SOC and potential cation exchange capacity, CEC), and (F3) nutrient supply (based on Ca<sup>2+</sup>, Mg<sup>2+</sup>, K<sup>+</sup>, P, pH, H+Al; Al<sup>3+</sup>, sum of bases and base saturation).

Based on a series of previous studies, the following important features were defined for the SoilBio protocol (i) the choice of the 0 to 10 cm depth as the diagnostic soil layer, sampled by the same procedure as for soil chemical fertility analyses and using air-drying and sieving (smaller than 2 mm) for the pretreatment of the soil sample; ii) time of soil sampling after harvest of the second crop, together with that for chemical analysis, facilitating the procedure for farmers (in Brazil, two summer cash crops, e.g. soybean and maize, are grown on most farms), and iii) use of the widely validated and accessible methodology developed by Tabatabai (1994), omitting toluene.

In order to make SoilBio accessible for farmers, Embrapa (The Brazilian Corporation for Agricultural Research) has capacitated commercial soil analysis laboratories through the Embrapa’s SoilBio Network. The reliability of the results across the country is ensured by the nationwide standardization of methods and protocols and appropriate proficiency testing. By January 2024, the SoilBio data bank contained 30,000 results of soil samples from 27 Brazilian states. Since the beginning, this database underlies and feeds the Brazilian Soil Health scoreboard.

Evaluating soil health status related to agronomical, environmental, and ecological aspects is a major scientific challenge. In addition, the optimal sampling season and sampling depth and the impacts of soil texture on an array of soil properties are also in question. To cope with these challenges, we conducted comprehensive field soil sampling campaigns and an intensive analysis to determine the most suitable properties for evaluating soil health. Soil samples were collected at six sites in two critical agricultural regions of Israel, comprising three different soil orders (Vertisols, Aridosols, and Inceptisols). We selected three adjacent plots at each site representing three agricultural land uses (perennial crops, annual crops, and non-cultivated lands). Each plot was sampled in two seasons (fall and spring) at three replicates in four soil depths (0–10 cm, 10–30 cm, 30–60 cm, 60–100 cm, N = 432). Overall, 94 soil properties were explored in this research based on soil and agronomy experts' opinions. A set of ANOVA and hierarchical clustering analyses were used to objectively reduce this long list of properties to determine the most land-use-sensitive properties for evaluating soil health in Mediterranean climatic zones. The statistical analysis suggested 22 soil properties that well indicate soil health statue, including traditional ones (e.g., mineral N, soil organic carbon, bulk density, etc.) and novel ones, such as free-living nematode and microbial community functionality indicators, the fluorescence emission of dissolved organic carbon, on-situ measurements as the diversity of weeds and visual soil assessments (VSA). Soil texture and depth significantly affected some of the selected soil properties. A possible way of accounting for soil texture effects is to develop relative indicators based on quantification of the relative proportion or performance of the chosen properties out of their overall population. In addition, the recommended sampling depth can be determined according to the sensitivity of the measured soil property to soil depth.

#### INTEGRATIVE LAND SYSTEM HEALTH EVALUATION FRAMEWORK FOR SUSTAINABLE SOIL STEWARDSHIP: INSIGHTS FROM A GRAZING SYSTEM ON AHUAHU, NEW ZEALAND

C. HYLAND

Agriscore Limited, Auckland, NEW ZEALAND

This research introduces an advanced soil assessment platform designed for application in commercial agronomy, providing a thorough evaluation of soil biogeochemistry, structural integrity, and microbial biodiversity. It includes the Cornell University / USDA NRCS soil health metrics, comprehensive nutrient testing of all macro- and micronutrients, and advanced soil microbial ecology methods in order to empower agricultural land managers as informed stewards of their soil ecosystems. A pivotal feature of the system is its molecular soil microbiome analysis, utilizing 16S rRNA and ITS region sequencing to detail the composition and abundance of soil microbial populations. This approach enables a nuanced understanding of the soil's biotic environment, which is vital for maintaining ecological balance and promoting agricultural sustainability. The data generated empowers land managers with the insights needed for informed management of soil in commercial agricultural systems. This novel approach encapsulates the essence of modern soil science, merging detailed laboratory data with practical applications in land management. A case study demonstrating the application of this land system health evaluation framework will be presented, detailing its implementation in a cattle and sheep grazing system on Ahuahu (Great Mercury Island), New Zealand. The study highlights the framework's utility in assessing and managing soil within pastoral agricultural systems.

### 4. Soil health in achieving the Sustainable Development Goals 4.03 125012 - Matching food security and environmental goals: phosphorus, a key global element

#### EXOGENOUS CARBON ALLEVIATED PHOSPHORUS ENVIRONMENTAL IMPACT THROUGH MEDIATING PHOSPHORUS DYNAMICS: A CASE STUDY OF CONTINUOUS MANURE INPUT IN SOUTHWEST CHINA

X. TANG<sup>1</sup>, C. ZHANG<sup>1</sup>, E. LE CARDE<sup>2</sup>, C. WANG<sup>1</sup>, B. LI<sup>1</sup>

<sup>1</sup> College of Resource, Sichuan Agricultural University, Chengdu, CHINA

<sup>2</sup> SAS, INRAE, Institut Agro,, Rennes, FRANCE

#### Background, Methods

Replacing chemical fertilizer with swine manure to reduce the input of phosphorus (P) fertilizer is a common practice in southwest China. Such practice takes a high risk of environmental impact, e.g. P leaching. Thus, to understand how annual P dynamics response to continuous manure and combined exogenous carbon (C) input is critical for P management. Soil inorganic phosphorus (P) fractions were studied in an 8-year continuous, randomized field trial involving rotating wheat-rice crops. The field trial comprised six treatments: triplicate control plots receiving chemical fertilizers only, and triplicate plots receiving chemical fertilizers and/or swine manure providing 150 to 1200 kg P<sub>2</sub>O<sub>5</sub>·ha<sup>-1</sup>. Soil incubation experiments were also conducted, involving addition of glucose or cellulose as exogenous carbon sources to test their effects on soil P dynamics with a view to reducing environmental damage from P leaching.

#### Results, Conclusions

Continuous application of swine manure increased soil P content and availability. P accumulated in the soil primarily as Fe-P during the first four years of manure application, but as Ca8-P during the next four years. The main driver of these changes in P fractions was soil total organic carbon (TOC; 31.5% contribution). TOC increased throughout the trial, rising faster in years 1–4 than years 4–8. Addition of cellulose to soil that had received high quantities of swine manure for eight years increased the moderately labile and moderately resistant organic P fractions but decreased the Ca8-P and Olsen-P fractions. This facilitated adsorption of high-activity inorganic P to the organic matter and limited the accumulation of Ca8-P. In terms of the risk of P leaching and of labile P content from soil was judged to be, optimized under a M2 treatment fertilization regime applying 10,300 kg ha<sup>-1</sup> y<sup>-1</sup> swine manure was the best treatment in our study. To reduce the risk of P leaching, it is recommended that additional cellulose-based organic matter (e.g., straw) be included in swine manure fertilization regimes.

The necessity of enhancing phosphorous (P) availability to crops while decreasing its migration in the environment, is well known. We propose to coat apatite with biodegradable polymers for the design of novel phosphorous fertilizers. We hypothesize that the biodegradable coating will specifically stimulate Phosphate Solubilizing Bacteria (PSB) and general bacterial activity and consequently, reduce local pH and thereby enhance phosphorous availability. Apatite was coated successfully with mucilage, a natural polysaccharide, extracted from chia seed. Mucilage loadings reached up to 15%, and the coatings were stable upon rinsing with water. The formulations were applied in sandy soil and the CO<sub>2</sub> emissions (indicating microbial activity) of the samples contacting uncoated apatite and of a commercial fertilizer (Triple Superphosphate, TSP) were similar to the control. The highest CO<sub>2</sub> emissions were detected from the samples containing apatite coated with mucilage, suggesting high microbial activity. TSP leaching from the soil was 3 orders of magnitude higher than the leaching from the mucilage coated apatite. The effects of general soil bacteria and specific PSB on the local pH of an apatite medium, was demonstrated. In the presence of glucose, general soil bacteria and PSB reduced solution's pH by ~0.6 and 1-1.7 units, respectively, and the pH reduction directly correlated to enhanced apatite P solubility. A similar, but more moderate trend, was obtained for bacteria in the presence of mucilage. Wheat plants were grown in pots containing sandy soil treated with mucilage (Muci), apatite (Ap), apatite+mucilage (Ap+muci) and TSP. The dry weight of the wheat was significantly higher for the 'Ap+muci' treatment, followed by the plants treated with Ap or TSP, while the control and Muci treatments resulted in significantly low weight. Olsen measurements (P plant availability test) indicated higher P concentrations in the 'Ap+muci' treated soil. These results support our working hypothesis that application of the apatite formulation to the soil enhance microbial activity which induces phosphate release from bacterial populations.

Soil phosphorus (P), a crucial element for ecosystem functioning and long-term plant nutrition, undergoes dynamic changes during soil recovery after disturbance affecting its forms and plant availability. Our approach includes 2 different scenarios of P degradation and recovery important at the global level as intensive land use or post-fire restoration.

Scenario 1. P degradation in post-fire scenarios. Organic and mineral soil layers of Mediterranean forests affected by wildfires (with different severities) and prescribed fires were sampled immediately and one year after fire. We observed an immediate rise in readily available P (orthophosphate) and <sup>31</sup>P-NMR spectroscopy revealed a notable transformation in P forms, particularly in the organic layer. Wildfires induced a profound and enduring effect on organic P, resulting in a large P mineralization (large increase of orthophosphate, mono- and diesters disappearance), even at low SBS, with orthophosphate dominance persisting after one year. Conversely, prescribed fire facilitated the recovery of organic P forms to pre-fire levels.

Scenario 2. Grassland restoration after intensive soil use. The recovery of semi-natural grasslands is considered a sustainable opportunity for P recovery in highly degraded soils. Here, we evaluated the accumulation and evolution of organic and inorganic P after a chronosequence of grassland reclamation. This work focused on abandoned croplands from Galicia (NW Spain), which were progressively recovered in a 45 yr chronosequence. Different soil P forms were identified in surface soils (0-5 cm). We observed a gradual soil recovery, and a progressive increase in P content and organic P forms, as well as in other physical-chemical parameters. Transformed grasslands recovered a significant proportion of the initial P content in the long-term (after 45 yr) reaching similar levels to those observed in seminatural forests or adjacent croplands. The increase in the organic P fraction can be considered as the result of high productivity due to climate, soil natural acidity and sustainable management (legume, slurry application), which favor plant growth and litter input.

#### ASSESSING SOIL PHOSPHORUS AVAILABILITY FROM STRUVITE APPLICATION IN NEW ZEALAND SOILS

F. DE LUCCA AGRELO, L. CONDRON, J. MOIR

Lincoln University- Department of Soil and Physical Sciences, Lincoln, NEW ZEALAND

Phosphorus (P) is a critical nutrient for plant growth and food production. With the projected global population growth to reach 9.5 billion by 2050, the demand for P fertilizers is expected to increase. Most of the P-fertilizers are derived from phosphate rock which is a finite source. Previous studies have shown that precipitated struvite ( $MgNH_4PO_4 \cdot 6H_2O$ ) is a promising sustainable alternative to traditional P-fertilizers. Nevertheless, little research has been done about its behaviour in New Zealand soils. The objective of this study was to assess changes in soil available P (Olsen-P) over time from struvite in a plant-less incubation with three contrasting soils in their anion storage capacity (ASC) compared with single-superphosphate (SSP), diammonium-phosphate (DAP), and reactive phosphate rock (RPR). Each fertilizer was mixed with the soil at a rate of 50 kg P/ha in replicates, and sampled at 3, 7, 21, 35, and 63 days of incubation. Averaged across sampling days, fertilizer type, and soil type, Olsen-P ranged from 6.0 to 45.0 mg/kg. Overall, Olsen-P increases were influenced by the interaction between soil type and fertilizer type. The addition of struvite generated increases in Olsen-P similar ( $P > 0.05$ ) to those of DAP and SSP in all the evaluated soils. For the soils with lowest and medium ASC, Olsen-P concentration of struvite addition were four and six times greater respectively, compared with the respective initial values, while for the high ASC soils, Olsen-P values from struvite doubled the initial value. These findings situate struvite as a promissory sustainable source of P especially for soils with high ASC where the application of conventional soluble fertilizers is limited due to its high reactivity with the soil components. To thoroughly evaluate the suitability of struvite as an alternative P-fertilizer source for New Zealand soils, further comprehensive research is necessary to gain a deeper understanding of struvite's performance in different soil conditions (e.i. pH) and its agronomic effectiveness for plant grow.

<sup>2</sup> University of Florida, Gainesville, USA

<sup>3</sup> North Carolina State University, Raleigh, USA

<sup>4</sup> University of Arkansas, Fayetteville, USA

Phosphorus (P) is an essential nutrient for animals, plants, and microbes; however, it could potentially harm the environment and its inhabitants when it is mined and used in unsustainable ways. It is estimated that > 40% of the world's arable land suffers from P deficiency, and finite rock phosphate sources could deplete in 50-100 years. Thus, establishing harmony between agriculture and the environment is critical. The Science and Technologies for Phosphorus Sustainability (STEPS) Center is a National Science Foundation-funded convergence research center with a goal of a 25% reduction in mined phosphates and a 25% reduction in losses from point and non-point sources to soil water resources could lead us to that desired P-balance. As part of this study, soils across three edaphic regions and varying P concentrations will be characterized using combinations of tools such as modified Hedley P-fractionation, P-XANES, and P-NMR that will allow for better understanding of the major forms of phosphorus in soil. Long-term application of animal manure and fertilizer in acidic soils (e.g., North Carolina), native P in muck soils (e.g., Histosol in South Florida), and tightly held P in alkaline calcareous Arizona soils makes the 'legacy P' a promising in situ P-resource. Our goal is to develop management strategies based on research findings that will help shift the P fertilization paradigm from "feed the soil" to "feed the plant".

#### ASSESSING GLOBAL FOOD SECURITY: THE IMPACT OF FERTILIZER SUPPLY RESTRICTIONS ON AGRICULTURAL PRODUCTION AND ENVIRONMENTAL QUALITY

Z. GONG <sup>1</sup>, J. BAKER <sup>1</sup>, P. HAVLIK <sup>2</sup>

<sup>1</sup> North Carolina State University-Department of Forestry and Environmental Resources and STEPS Center, Raleigh, USA

<sup>2</sup> International Institute for Applied Systems Analysis(IIASA)-Biodiversity and Natural Resources Program (BNR), Laxenburg, AUSTRIA

Fertilizers are essential for agriculture, accounting for about 60% of yield increases in staple crops over the past 50 years and alleviating food security concerns. However, recent supply chain disruptions due to COVID-19, geopolitical tensions, and trade policies have precipitated a global fertilizer crisis, threatening food security as prices soar.

This crisis endangers the balance between farmer compensation and consumer affordability. Reduced fertilizer availability increases costs for farmers, particularly those cultivating essential crops like wheat, leading to heightened food prices and deepening the hunger crisis. Conversely, overuse of fertilizers results in environmental degradation, including eutrophication and greenhouse gas emissions, posing further challenges to sustainable agricultural practices.

Our research delves into the implications of nitrogen and phosphorus fertilizer supply constraints on food production, trade, land management, and environmental quality. This research will build on efforts further to develop Global Biosphere Management Model (GLOBIOM). Our approach incorporates both spatial and behavioral heterogeneity at regional scales, connecting regional production decisions with global policies.

We built our model with detailed economic, land use, and environmental data from the U.S. region. It represents the agricultural production of 18 crops and seven livestock types, processed for food, feed, and bioenergy markets. We explore various scenarios, including trade restrictions, sustainability policies, and climate change impacts.

Preliminary results indicate global trade restrictions, like export tariffs on fertilizers and quantity constraints, affect U.S. fertilizer consumption, agricultural outputs, and food security. Our future analysis will examine market dynamics under these scenarios and their interplay with other global change drivers.

This work contributes significantly to the modeling of fertilizer policy and food security, offering insights into domestic and global impacts of supply-side constraints. It highlights the importance of integrated, spatially heterogeneous approaches to understanding and responding to complex interdependencies between fertilizer management, food production, and environmental sustainability. This also provides a robust framework to inform policies safeguarding food security while mitigating environmental impacts, emphasizing needs for synchronized global and regional strategies.

**PHOSPHORUS IN THE SYSTEM SOIL – CROPS – WATERS: NEW INSIGHTS FROM A DECADE OF GERMANY-WIDE RESEARCH PROGRAMS**

P. LEINWEBER

University of Rostock, Rostock, GERMANY

In Germany the issue of agricultural phosphorus (P) use has received great public recognition in the past decade for two reasons: (1) concerns about future P-shortage, fuelled by publications of a “peak phosphorus” and expected global P-shortage (e.g. Cordell & White, 2014), (2) the non-sustainable agricultural P usage, oversupply to soils, and deterioration of water quality in freshwater and marine environments. Governmental boards and funding agencies have set up research programs towards finding solutions for a more sustainable P use, two of which will be presented. The Leibniz ScienceCampus Phosphorus Research Rostock (2014-2024; <https://wissenschaftscampus-rostock.de/home.html>) has run two graduate schools in which 26 PhD candidates conducted multidisciplinary P-research projects. A similar multidisciplinary approach was the basis of the research program InnoSoilPhos (2015-2024; <https://www.innosoilphos.de/>) in the frame of the BonaRes Soil Research Program of German Ministry for Education and Research. A few examples of soil-related research outcomes shall prove the author’s thesis that the P issue can be managed sustainably: (1) Current P fertilizer recommendations are too high, saving P by less fertilizer does not mean yield depressions. (2) The legacy P pool in soil, even the mobile fraction, is sufficient for many harvests at omitted P fertilization. (3) The P binding mechanisms are understood at the atomic and molecular scale, offering ways to overcome strong fixation and getting P into solution. (4) Proper crop rotations and even weeds can mobilize P for the main field crop. (5) Many P recycling technologies are at hand, and the P recycling materials release the P slowly, reducing the demand for mineable P resources and the risk of P transfer to waterways. (6) Finally, P governance and policy instruments have been proposed for a better P management. In the light of these new research results, currently, the P issue appears less dangerous than a decade before.

#### OPTIMIZING AGRICULTURAL PHOSPHORUS SUSTAINABILITY: INSIGHTS FROM LONG-TERM FERTILIZATION STRATEGIES AND CLIMATE CHANGE IMPACTS IN CHINA

Y. WANG, S.Q. WANG, H. CHEN

Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

Soil phosphorus (P) is unevenly distributed across regions and ecosystems. Historical excessive P fertilization to maximize crop production has led to the accumulation of soil P in some regions. Accumulated soil P is susceptible to loss to water bodies through surface and subsurface runoff, leaching and erosion, which contribute to eutrophication. In 2015, the Chinese government introduced the 'Action Plan for Zero Growth in Fertilizer Usage by 2020', especially for Nitrogen (N) and P, while enhancing its efficacy. This initiative seeks to foster modern agricultural practices prioritizing high productivity, product safety, resource conservation, and environmental sustainability. In this context, we conducted a comprehensive series of long-term field experiments to compare optimal fertilization strategies in the current agricultural system and future climate change scenarios. For instance, through two 13 years of field experiments, we found that annual planning of P fertilizer in paddy-upland rotation farming can reduce fertilizer application and P loss, without affecting crop yields, highlighting the importance of recognizing soil legacy P as a valuable resource. However, to ensure future crop and environmental gains, climate change must be considered a key factor in shaping sustainable strategies for phosphorus management. Our findings from two long-term rice Free Air Carbon Dioxide Enrichment (FACE) experiments, conducted over 15 and 9 years, further suggest that increased transfers of plant-available P from biological, biochemical, and chemical sources under anthropogenic changes are insufficient to compensate for reductions in plant-available phosphorus under long-term exposure to elevated CO<sub>2</sub>. Hence, addressing the challenge of balancing food security and environmental goals will continue to be a significant challenge in the Agricultural System.

<sup>2</sup> ICL Specialty Fertilizers, Murcia, SPAIN

Phosphorus fertilizer supply encounters challenges due to scant phosphate rock mines and stringent quality regulations. Recycling high phosphorus wastes is an appropriate alternative to ensure nutrient supply for crops and circular economy strategies. In this work conducted in South East Spain conventional phosphorus fertilization was partially substituted with alternative sources such as meat-bone meal (MB), sludge (S) and its combination (SMB) in a wheat agroecosystem. Results showed that crop yield can be maintained by partially replacing conventional chemical fertilizers with said alternatives. S and the organomineral combination SMB generated higher bioavailable phosphorus compared to traditional treatments, attributed to elevated phosphatase activity. During germination and flag leaf stages, an increase in phosphatase activity was observed in the organomineral treatments, concurring with the highest microbial biomass in these treatments. Significant differences between treatments in soil microbial biomass were observed in flag leaf stages, S and SMB showed the highest microbial biomass. Amplicon sequencing revealed that bacterial and fungal community composition was influenced by crop phenology, while fertilization treatments effect was less pronounced. This organo-mineral fertilization approach emerges as a sustainable method for crop production and soil health improvement, emphasizing the dominant role of crop phenology in shaping soil microbial communities.

#### MAPPING PHOSPHORUS AVAILABILITY AT FIELD SCALE USING A COMBINATION OF DIFFUSIVE GRADIENTS IN THIN FILMS (DGT) AND SYNCHROTRON X-RAY FLUORESCENCE MICROSCOPY (XFM)

C. DOOLETTE<sup>1</sup>, E. SMITH<sup>1</sup>, C. MOENS<sup>2</sup>, P. KOPITKE<sup>3</sup>, E. LOMBI<sup>1</sup>

<sup>1</sup> University of South Australia, Mawson Lakes, AUSTRALIA

<sup>2</sup> KU Luven, Heverlee, BELGIUM

<sup>3</sup> The University of Queensland, St Lucia, AUSTRALIA

#### Introduction

The diffusive gradients in thin-films (DGT) technique<sup>3</sup> is commonly used to estimate the potentially bioavailable concentrations and distribution of nutrients and contaminants in the environment. This method correlates strongly to plant available nutrients because it mimics plant nutrient uptake by acting as an infinite sink. This technique has been used to obtain two-dimensional (2D) images of labile P concentrations or P fluxes in soil using Laser Ablation (LA) ICP-MS. However, conventional DGTs are tedious to prepare and difficult to prepare at a scale (10s of cm<sup>2</sup>) relevant to field scale observations.

The aim of this study was to develop and test a new large, simple to prepare and robust DGT that allows to map the spatial distribution of labile P at field scale in combination with XFM.

#### Material and Methods

The novel DGT device is based on a new binding layer where Metsorb is deposited on a sheet of polyimide film coated with an acrylic adhesive. The resulting binding layer can be 100s of cm<sup>2</sup> and is easy to prepare and extremely robust, making it ideal for field deployments. These large DGT devices were tested in a field experiment in South Australia where different P strategies were applied. The binding layers were analysed at the XFM beamline at the Australian Synchrotron.

#### Results

The results of preliminary experiments showed that P quantification by XFM provided similar results to LA-ICP-MS. This study showed that reaction of different forms of P fertilizers near the point of application (often called the fertosphere) are complex and this novel DGT design, with a gel-free binding layer that allows analyses through synchrotron XFM, can provide an easy and convenient method to visualize P availability in 2D.

<sup>2</sup> Norwegian University of Life Sciences, Ås, NORWAY

Norway faces many challenges for best managing phosphorus (P) in the agricultural landscape, which include large regional differences in climates, soils, production systems and P balances. These differences result in diverse drivers and processes controlling P losses from the landscape and management needs for both water quality and food production goals. In the past, a national policy was implemented to prioritize cereal production in the eastern part of Norway that has suitable climate and soils, and livestock production in the west that is not suitable for cereal production due to high precipitation. The policy helped with food self-sufficiency in the country but has led to a dilemma with manure P surplus in the west. Today, the cereal production areas typically have soil erosion problems that degrade soil quality and cause large amounts of particulate P loss associated with tillage, and the livestock production areas have problems with soil P buildup, loss of dissolved P, and low efficiency of added P for crop production. Notably, P losses from different regions have been monitored since 1990s in 10 representative agricultural catchments across Norway (JOVA program) to report temporal and spatial water quality trends in the streams and assess the impacts of management. Moreover, policy efforts and economic incentives have been made or are being developed to reduce livestock density, avoid winter manure applications, and promote the use of conservation tillage, cover crops and wetlands. The effectiveness of some of the measures to reduced P losses have been tested and demonstrated in the field. In this presentation, we aim to give an overview of (1) the regional differences in soil P distribution and P losses from agricultural catchments to water, (2) the effectiveness of selected mitigation measures to reduce P losses, and (3) future needs for P research and management.

#### MANAGING LEGACY PHOSPHORUS IN SOILS FOR MAXIMIZED CROP PRODUCTION WITH MINIMIZED ADVERSE WATER QUALITY IMPACTS IN THE GREAT LAKES BASIN

T. ZHANG, Y. WANG, C. TAN

Harrow RDC, Agriculture and Agri-Food Canada, Harrow, CANADA

#### **Body**

Soils derived from glacial parent materials are fertile and highly productive in the Great Lakes basin. Intensive fertilization excessive to crop removal resulted in build-up of legacy P in soils (LPS), that not only becomes a predominate source of P loading to the lakes but also makes lag of water quality improvement with mitigation efforts of BMP implementation. In order to gain in-depth understanding of the nature of LPS and develop efficient management practices that enable farmers to maximum crop production with minimized adverse impacts on lake water quality, we conducted systematically studies by focusing on the Lake Erie basin, the one with most water quality concerns among the five Great Lakes, in past 25 years. We assessed the stocks and availability status of LPS, developed environmental soil P testing methods, and assessed typical/newly proposed management practices based on which BMPs were developed for efficient use of LPS. The LPS was estimated with 589 kg ha<sup>-1</sup>, which would supply crops for approximately 40 years without further addition if fully used. Degree of soil P saturation is a practically meaningful procedure for P loss assessment with potential for agronomic P calibration. Legacy P in clay loam soils sustained consistently crop yields for 16 years relative to continuous P addition. Soil test P declined at a rate of 3.1 mg ha<sup>-1</sup> year<sup>-1</sup>, with critical values observed at 10.3-17.1 mg kg<sup>-1</sup> for various crops. In sandy loam soils, however, a booster of fertilizer P addition is required to ensure optimum crop growth even if in soils that are very high in LPS. Use of LPS decreased soil P losses in runoff water by 33%, which was further enhanced by winter cover crop combined with controlled drainage and sub-irrigation. Optimized utilization of LPS can be an effective approach to sustain crop production and improve farming profitability and meanwhile to ultimately reach the goal of agri-P loading reduction to water bodies in Great Lakes basin.

<sup>3</sup> National Agricultural Experimental Station for Soil Quality, Suzhou Academy of Agricultural Sciences, Suzhou, CHINA

The existing form of phosphorus (P) in the soil is key for the bioavailability, which influence the utilization and loss risk of P. A better understanding of fertilization strategy on regulating P bioavailability and loss risk is urgently required to improve P utilization and reduce P input. In this study, soils of six different fertilization treatments from a long-term experiment in Suzhou (started in 1980) were collected: CO(no fertilizer), CNK (chemical fertilizer of N & K), CNPK (chemical fertilizer of N, P & K), MO (only manure), MNK (manure + chemical N and K fertilizer), MNPK (manure + N, P and K fertilizer). Results showed that organic fertilizer application elevated soil organic carbon (SOC), Olsen-P and TP contents. The increase in Olsen-P of MNPK treatment was even greater than the additive effect of CNPK and MO treatments. Soil organic P content and percentage increased under organic fertilizer treatments compared to inorganic fertilizer treatments, and NaOH-P<sub>o</sub> was the dominant. OM-Fe (Al)-P accounted for about 34.6-70.0% of NaOH-P<sub>o</sub>. OM-Fe (Al)-P showed a significant positive correlation ( $P < 0.05$ ) with DDI (the degree of decomposition index), amorphous Fe and Al, which indicate that the application of organic fertilizer promoted the DDI of soil OM, which in turn elevated the amorphous Fe and Al content, and hence the OM-Fe (Al)-P content. On the other hand, organic fertilizer application significantly increased soil colloidal P content through co-precipitation of organic matter with Fe/Al. This may increase the P loss risk due to the characteristics of mobility and relatively large specific surface area of colloidal particles. This study suggested that organic fertilizer application may act as a double-edged sword. Organic fertilizer with proper C/P ratio is key to balance the soil P availability and environmental risk.

**Keywords:** organic fertilizer, soil P bio-availability, soil colloidal P, amorphous Fe and Al

Starter fertilizer phosphorus (P) is crucial to crop production, but its application beyond what is necessary for plant growth can result in high soil P concentrations and increase P loss from agricultural land to water. The objectives of this work were to assess the effects of increasing rates of starter fertilizer P on: (1) silage corn dry matter (DM) yield and plant P uptake at early growth stages; and (2) changes in soil P. We conducted 20 trials from 2018 to 2021 with increasing starter P rates (0, 5, 10, 15 and 20 kg P/ha) and manure on farmers' fields across the Fraser Valley (British Columbia, BC, Canada). In 2018, DM weight at the 6-leaf stage was affected by starter P in all sites, and the response curve was described by a linear-plus-plateau model with critical starter P of 5.0 and 7.5 kg/ha. In 2019, corn DM weight at early growth stages was not affected by starter P. In 2020 and 2021, at early growth stages of silage corn, DM weight response to starter fertilizer P was not significant, except at one site where the critical rate varied between 5 and 7.5 kg P/ha. Corn DM yields at harvest (20–27.2 Mg/ha) during the four growing seasons were in the optimum provincial range in sites with excess P, with the exception of three sites, one two low initial soil P concentrations and the other with waterlogged soils. These results showed that starter fertilizer P could be reduced or even eliminated completely without affecting the growth of young plants and yield at harvest, decreasing the need for off-farm P inputs and the risk of P loss to the environment.

**AGRONOMIC AND ENVIRONMENTAL OUTCOMES IN RESPONSE TO PHOSPHORUS PLACEMENT IN CONSERVATION-TILLAGE SYSTEMS AND THE ROLE OF SOIL-WATER AND ROOT DISTRIBUTION ON PHOSPHORUS UPTAKE BY CORN AND SOYBEAN**

F GERARDO FERNANDEZ

University of Minnesota, St Paul, USA

Broadcast phosphorus (P) applications without soil mixing result in P stratification in the soil profile with greater concentrations near the surface. Some have hypothesized that this stratification is a problem because it forces crops to obtain P from the surface layer that is more vulnerable to drying. For this reason, some have proposed that a subsurface band application might be advantageous because P is placed where there is presumably more available water. Studies were conducted continuously in the same fields for 9-yrs with various P rates broadcast on the soil surface or sub-surface banded 15 cm below the crop-row in both no-till and strip-till. Plant P uptake along with measurements at several soil depth increments (both in the crop-row and between-rows) of soil moisture, root-diameter, -length and -surface density, and soil P were conducted throughout the growing season. The study showed that strip-till improved grain production relative to no-till, but there was no effect of P placement. Root-density was highest in the surface layer and quickly declined with soil depth for both the crop-row and between-rows. Water content was relatively uniform within the top 40 cm of the soil, and while the surface layer dried more during prolonged periods without rain, water content was replenished more in the surface than the subsurface with typical intermittent rainfall. There was no evidence of improved efficiency or potential to reduce P fertilization rates with subsurface band applications. Regardless of P placement, apparent P uptake (change in soil P levels over time) was greatest in the surface layer between-rows. The study determined that for each soil core taken in the P band two to three cores between-rows are needed in a composite to correctly determine the fertility of fields with banded P that created horizontal stratification with bands of high- and low-P across the field. While there were no agronomic benefits, P runoff was substantially reduced with subsurface-banded P even at high-P fertilizer rates.

#### EFFECT OF PHOSPHORUS-ENRICHED BIOCHAR FROM REAL TREATED WASTEWATER (RTWW) ON SOIL-SUNFLOWER (*HELIANTHUS ANNUUS L.*) SYSTEM

S.M. MUSCARELLA<sup>1</sup>, V.A. LAUDICINA<sup>1</sup>, L. BADALUCCO<sup>1</sup>, G. MANNINA<sup>2</sup>, J. NIETO<sup>3</sup>, A. DELGADO<sup>3</sup>

<sup>1</sup> University of Palermo, Department of Agriculture, Food and Forest Sciences, Palermo, ITALY

<sup>2</sup> University of Palermo, Department of Engineering, Palermo, ITALY

<sup>3</sup> University of Seville, Department of Agronomy, Sevilla, SPAIN

Due to the increasing world population, it is necessary to find new source of nutrient for plant grown. Phosphorus, a limited resource, can be recovered from treated wastewaters using biochar, a pyrolysis product. The aim of this study was to evaluate the ability of P-enriched biochar in acting as P fertiliser for sunflower cultivation (*Helianthus annuus L.*) system. The biochar was enriched using real treated wastewater at a pilot-scale wastewater treatment plant of the Water Resource Recovery Facility of Palermo University. Two types of biochar (B440 and B880), obtained from the same biomass by pyrolysis at 440°C and 880°C, respectively, were used. The experimental design involved the use of calcareous and not calcareous soils, both deficient in P. Four treatments were performed: a control without P, a control with P applied as KH<sub>2</sub>PO<sub>4</sub> at a dose of 50 mg of P per kg of dry soil, a treatment with biochar B440, and another one with biochar B880, both applied to add 50 mg of P per kg of dry soil. The experiment lasted (122 days) and was carried out in a growth chamber. Sunflower was chosen as test plant due to its high P requirement and susceptibility to nutritional deficiencies. The study included extensive investigation such as biochar ATR-FTIR spectra, P release kinetics analysis, a germination index, phytotoxic risk assessment, and the evaluation of biochar's impact on soil and sunflower plants. Biochar B440 released P slower than B880. Germination tests indicated that both biochar positively influenced germination and root growth of lettuce without phytotoxic effects. Notably, the germination index increased by 15% with P-B440 and 20% with P-B880 compared to the control. However, when applied to soil, enriched P-biochar did not affect available P forms and P uptake of sunflower plants did not exhibit differences between soil amended with enriched biochars and control. Anyway, the P replacement value of enriched biochar ranged from 2 to 12% of inorganic fertilizers.

<sup>4</sup> School of Agriculture and Food Sustainability, The University of Queensland, Brisbane, AUSTRALIA

Higher soil temperatures hasten phosphorus (P) sorption and reduce P availability for crops, but the effects of soil warming on initial P sorption rate and P use efficiency (PUE) are unclear. We quantified the fate of P on a black Vertosol, using in situ microdialysis incubations over 165 days, at four temperatures (10, 20, 35, 50 °C), five P application rates (equivalent to 0 (control), 50, 100, 200, 400 kg ha<sup>-1</sup> at 10 cm depth), with two P forms: finely ground triple super phosphate (TSP) (Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub>·H<sub>2</sub>O) and dissolved KH<sub>2</sub>PO<sub>4</sub>. On average, PO<sub>4</sub>-P availability at 50 °C was 53 % (TSP) and 64 % (KH<sub>2</sub>PO<sub>4</sub>) lower compared to 10 °C, across all P rates except the control. There were significant temperature effects on PO<sub>4</sub>-P for both P forms, but for different reasons. Decreasing PO<sub>4</sub>-P at 35 and 50 °C caused significant temperature effects sooner and more consistently for KH<sub>2</sub>PO<sub>4</sub>. However, temperature effects from TSP were attributed to an increase in PO<sub>4</sub>-P at 10 and 20 °C at 200 and 400 kg ha<sup>-1</sup>. We then simulated the KH<sub>2</sub>PO<sub>4</sub> incubation using APSIM Next Generation, which successfully captured variability in available P (95-97 %) with lower accuracy at higher P and temperatures (82 %). We found that historic temperature data of subsoil (100 cm) which increased at a rate of 0.24 °C per year (1983-1995) while topsoil (5-10 cm) temperature reached 50 °C during peak periods (2013-2022). We found that the impact of cumulatively increasing soil temperatures on PUE demands attention, including reporting of soil temperature and testing on a wider range of soils is required. APSIM is emerging as useful tool to predict P availability and inform management (timing, placement and P form, cover crops).

<sup>2</sup> Institute of Crop Science and Resource Conservation (INRES)-Soil Science and Soil Ecology, Bonn, GERMANY

The extreme conditions of the Chilean Atacama Desert preserve life's fingerprints. This is particularly the case for its subsoil which provides enhanced shelter for microbial communities. Our study sampled at Paposo four pits at 10 cm intervals, reaching a depth of 2 m, along a transect with increasing distances from the coast and thus aridity. Subsequently sequential P fractionation and <sup>18</sup>OHCl-Pi analysis were conducted to explore the biogeochemical transformation of top- and subsoil P. None of the measured values of <sup>18</sup>OHCl-Pi fell within the 'equilibrium' range. This highlighted that soil phosphate present had undergone only partially biological P cycling. Nevertheless, variations were observed at different depths. In the fog-nourished zone, situated within 3.5 km from the coast, the highest <sup>18</sup>OHCl-Pi value of 16.6 ‰ was found at the surface, and thereafter gradually decreased with increasing depth. However, a relatively higher value of 15.8 ‰ was detected at a depth of 80-90 cm, pointing to wetter period in the past. Within the inland areas (>10 km from the coast) with only rare rainfall events, a sampled fan (at 1450m) exhibited an increase of <sup>18</sup>OHCl-Pi up to 13.1 ‰ its second layer (10-20 cm), while values remained stable with depth in the active section. Our investigation of subsoil P cycling provides novel insights into the historical presence and variation of (microbial) life in association with fluctuations in climatic driven soil wetness conditions.

#### 4.04 131145 - Dynamics and functions of soil organic matter under new and traditional amendments

##### SHORT TERM EFFECT OF NOVEL BIOBASED FERTILISERS FROM FRUIT AND VEGETABLE RESIDUES ON SOIL FUNCTIONING

C MONDINI<sup>1</sup>, T SINICCO<sup>1</sup>, F AMERY<sup>2</sup>, E RONCHIN<sup>1</sup>

<sup>1</sup> CREA Research Centre for Viticulture and Enology, Gorizia, ITALY

<sup>2</sup> Institute for Agricultural and Fisheries Research, Plant Sciences Unit, Merelbeke, BELGIUM

The H2020 Rustica project aims to produce novel biobased fertilisers (BBF) from fruit and vegetable residues to reduce mineral fertilizer dependence, improve soil health, and tackle soil organic matter loss. The novel BBF are microbial biomass (MB) from microorganisms cultivation, insect biomass (IB) and frass (IF) from insect farming, and biochar (BI) from pyrolysis.

The application of such new materials can have undesired impacts on soil and, consequently, an exhaustive assessment of their effects on soil functioning is needed.

For this purpose, MB, IB, IF, and BI were applied at a rate of 0.5% to a soil and incubated in the laboratory for 30 days. CO<sub>2</sub> and N<sub>2</sub>O emissions were measured continuously throughout the incubation. After 2, 7, and 30 days, soil samples were analysed for extractable NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, P, organic C and N (EN), Olsen P, and soil microbial biomass C and N.

The percentages of added C mineralised after 30 days were 0.8%, 25%, 47% and 53% for BI, IF, MB and IB, respectively. The outstanding stability of BI supports its effectiveness to foster soil C sequestration. The different degree of degradability of BBF is supported by their properties in terms of oxygen uptake ratio, water soluble C and N. This is reflected by N<sub>2</sub>O emissions, with higher levels observed in soil treated with IB and MB.

Biochar and IF did not cause an increase in N availability. On the other hand, IB and MB caused an enhancement in EN compared to the control of 7% and 13%, respectively, suggesting their relevance as N fertilisers.

Soil microbial biomass was increased by MB and IB, and for a lesser extent by IF.

BBF showed large differences regarding their impact on soil quality. As such, they can be applied to exert different functions (mineral fertilizers substitution, soil quality maintenance, climate change mitigation). Moreover, results can be useful to identify management options to maximize BBF potential and avoid detrimental effects.

#### THE IMPACT OF NEW BIO-BASED FERTILISERS AND CONVENTIONAL AMENDMENTS ON SOIL ORGANIC MATTER AND SOIL HEALTH DYNAMICS: A MULTI-YEAR LIVING LAB APPROACH

P. FORRESTAL, D. KINSELLA, J. MURPHY

Teagasc, Environment, Soils and Land Use Department, Wexford, IRELAND

The loss and degradation of soils can occur over relatively short timeframes for example, due to erosion. However, improvements in soil chemical, physical and biological health, including organic matter tend to occur gradually over a number of years or decades. The application of amendments such as bio-based recycled fertilisers is an avenue for returning carbon and nutrients to soils while reducing reliance on conventional imported mineral fertilisers. While bio-based recycled fertilisers contain nutrients, frequently the nutrient profile is not in the correct proportion to match crop and soil fertility requirements. As a result, at a practical agronomic level, when using these amendments fertilisers there is often a need to supplement to crop and soil requirements using mineral fertilisers. In 2019, to help build confidence for farmers to undertake substitution of mineral fertilisers with new bio-based recycled amendments a multi-year bio-based fertiliser living lab and demonstration was established on a moderately drained sandy loam grassland site at the Teagasc, Johnstown Castle Soils, Environment and Land Use Research Centre in the South East of Ireland. At this living lab over the past five years a mineral fertiliser only fertiliser programme has been compared to fertiliser programmes that displace a portion of the mineral fertiliser with cattle slurry, dairy processing sludge, ash and struvite. A no fertiliser treatment is also included. Soil pH, fertility, soil organic matter, soil biology indicators and grass yield performance have been measured over the five year period. The use of new amendments are being demonstrated to farmers and advisors as part of the EU Horizon funded NOVAFERT project while new collaborations to advance soil health improvement have developed on foot of the long running living lab. Initial results indicate that several bio-based amendments can maintain grass yield and build soil fertility and improve soil health indicators. Full results including effects on soil organic matter will be presented.

### NOURISHING THE SOIL: DECODING MICROBIAL RESPONSES TO SPRING-PLANTED COVER CROPS

G. HIDROBO <sup>1</sup>, A. FERNANDEZ <sup>1</sup>, E. MOSES <sup>2</sup>, M. SCHAEDEL <sup>3</sup>, J. GROSSMAN <sup>1</sup>

<sup>1</sup> University of Minnesota, Saint Paul, USA

<sup>2</sup> University of Illinois, University of Illinois at Urbana-Champaign, USA

<sup>3</sup> Cornell University, Ithaca, USA

Over the past three decades, organic farming has experienced a significant global surge. In the USA, the latest national survey in 2019 revealed the presence of 5.5 million acres. Organic farming poses challenges in managing soil fertility and nutrient availability, both crucial factors for robust crop production. Cover cropping is widely used in organic farms to provide a source of carbon (C) and nitrogen (N) to the soil among other multiple benefits. The impact of added C and N from cover crops on beneficial microorganisms remains understudied. This is crucial for predicting soil functions like mineralization through which nutrients become available for following cash crops. Our objective was to assess the impact of decomposing spring-planted cover crops on microbial biomass, C/N-cycling enzyme activity and microbial communities.

Cover crops were established in early May and terminated in mid-July 2021 and 2022 at two locations in Minnesota-USA, after which broccoli was transplanted. Treatments included a legume, a forb, a legume/grass mixture, and two controls: a weedy fallow and weed-free fallow. Microbial biomass C/N and four hydrolytic enzymes (Beta-glucosidase, N-acetyl glucosaminidase, Cellobiohydrolase, and Phosphatase) were measured from fresh soil samples. Legume-inclusive treatments showed higher microbial biomass at both locations (Figure 1), suggesting the benefits of incorporating legumes to promote plant-microbial symbiotic relationships.

Microbial biomass as well as enzyme activity was highest 45 days after cover crop termination, which may indicate that nutrient mineralization aligned with cash crop nutrient uptake, representing successful cover crop integration. No enzyme activity differences were observed between cover crop treatments, including the weedy control; however, all of these showed higher values compared to the weed-free control. Preliminary results suggest warm-season cover crops, particularly legume-inclusive options, have the potential to enhance N-fertility goals by promoting active microbial communities. Results from DNA amplicon sequencing for both bacterial and fungal communities are underway to better characterize microbial operational taxonomic units, and correlate their abundance with soil biological functions.

**UNLOCKING THE POTENTIAL: THREE-YEAR FIELD STUDY INVESTIGATING THE IMPACT OF THE ORGANIC WASTE RECYCLING ON SOIL HEALTH, NUTRIENT UPTAKE, AND CARBON MANAGEMENT IN AGRICULTURE**

M. GRIGATTI

University of Bologna Dept. of Agricultural and Food Science (DISTAL), Bologna, ITALY

The EU promotes organic waste recycling in agriculture for soil health and nutrient supply as an alternative to chemical fertilization. However limited data exists on medium- to long-term benefits.

This study investigated the plant nutrient uptake, the soil organic matter (SOM) variation, and the effect on soil functions using the Carbon Management Index (CMI) over a 3-year field plot test.

Furthermore the natural  $^{13}\text{C}$  abundance (delta  $^{13}\text{C}$ ) of compost and soil carbon was used to assess the fate native and applied organic carbon.

To do this two agronomic pathways were compared: continuous and pulsed compost application of three types of compost: from bio-waste (BWC), from anaerobically digested bio-waste (DC) and from urban/agro-industrial sludges (SC), along with a chemical N-P-K fertilizer (Chem) and a unamended control (Ctrl).

In Path 1, the N-EAR (%) was highest in BWC (112) > DC (105) > SC (74). Indicating SC performed lower N-use efficiency, consistent with its high C:N ratio and biological stability (OUR).

The study revealed Path 2 performed high relative agronomic efficiency (N-EAR% vs. Chem): SC (118) > DC (114) > BWC (109), indicating a general benefit in the use of the chemical N fertilizer following basal compost application.

Continuous compost application led to constant SOM accumulation (10-40%), while pulsed application preserved the native soil organic carbon. The CMI highlighted increased SOM functionality, supporting composts as effective fertilizer substitutes.

Overall, the organic treatments showed higher N efficiency with chemical fertilizer synergy and a good ability to supply P over three years.

The delta  $^{13}\text{C}$  of treated soil proved the either carbon accumulation from compost or the preservation of the native soil organic carbon (Figure 1).

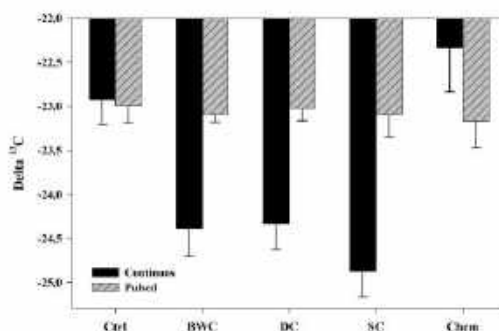

Figure 1 -  $\delta^{13}\text{C}$  values of soil following three years of cultivation under various treatments in both continuous and pulsed pathways

#### EFFECT OF BIOCHAR-TC (PYROCHAR) AND BIOCHAR-HTC (HYDROCHAR) AMENDMENTS ON GREENHOUSE GAS EMISSION AND WATER QUALITY IN TOMATO PRODUCTION

C. JEONG <sup>1</sup>, K. RO <sup>2</sup>, M. LEE <sup>3</sup>, J. WANG <sup>4</sup>

<sup>1</sup> Louisiana State University AgCenter, Red River Research Station, Bossier City, USA

<sup>2</sup> USDA - ARS, Coastal Plains Soil, Water & Plant Research Center, Florence, USA

<sup>4</sup> Louisiana State University AgCenter, School of Plant, Environmental and Soil Sciences, Baton rouge, USA

When producers grow tomatoes in greenhouses, they tend to use excess fertilizer and water to maximize yields. This excess leads to the rapidly accumulating carbon, nitrogen, phosphorus, and salts in the growing media. Recently, carbon-rich products from thermal carbonization (Biochar-TC) and hydrothermal carbonization (Biochar-HTC, hydrochar) have been proposed as soil amendments to mitigate greenhouse gas emissions and improve water quality in leachate. This research compared the amendment impact of two different types of biochars on CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O emissions and nutrient leaching in tomato production. Fluxes of CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O were measured in the tomato-growing pots using a manual static chamber method during the tomato-growing season. The chambers are made of cylindrical polyvinyl chloride (PVC) 15 cm in diameter and 20 cm in height. The temperature and soil moisture were measured continuously using sensor pups, and the results were transferred to a data retriever. Gas samples were measured at 0, 15, 30, 45, and 60 min after the chamber closure. The collected gas samples were analyzed using a gas chromatograph (model 8610C, SRI Instruments). Nitrous oxide was detected with the electron capture detector (ECD) operated at 325°C, and CO<sub>2</sub> and CH<sub>4</sub> were measured with a mechanized interface with a flame ionization detector (FID). These results demonstrate that Biochar-TC application significantly decreased N<sub>2</sub>O emission compared to the emission from the control treatment. Leaching water was collected from each tomato growing pot daily, and total phosphorus concentration and electrical conductivity (EC) were, on average, 25% and 21 % lower from the Biochar-TC treatment and 8% and 1.8 % lower from the Biochar-HTC (Hydrochar) treatment, respectively, compared with the control. We observed that two different types of soil amendments did not significantly improve tomato production.

#### FROM WASTE TO GROWTH: UNRAVELING ROSE WASTE COMPOSTING PATTERNS AND EVALUATING THE EFFECT ON CUT ROSES IN KENYA

E. DE NIJS<sup>1</sup>, B. JANSEN<sup>1</sup>, R. BOL<sup>2</sup>, A. TIETEMA<sup>1</sup>

<sup>1</sup> University of Amsterdam, Institute of Biodiversity and Ecosystem Dynamics, Amsterdam, THE NETHERLANDS

<sup>2</sup> Institute of Bio- and Geosciences, Agrosphere (IBG-3), Forschungszentrum Jülich GmbH, Jülich, GERMANY

Composting is widely recognized as a sustainable waste management strategy and a valuable soil amendment to enhance SOM content in high-production agricultural soils. These are valuable assets for the Kenyan rose cultivation sector to further improve their circular economy waste-based objectives. However, little is known about green waste, and specifically rose waste, degradation patterns during composting and its subsequent effect on cut rose yield and quality. This integrated study combines molecular insights into rose waste composting and potential co-metabolism of ligneous materials using Py-GC/MS with findings from an 18-month commercial-scale field-experiment in Kenya. This approach not only enhances our understanding of molecular conversions of lignocellulosic waste during composting, but also evaluates the potential of sustainable practices to boost horticultural productivity. Additionally, it gives an outlook on the impact of compost-originated OM in soils and provides valuable perspectives on its role regarding yield and quality of cut roses. Several compost mixtures were followed closely and temporal trends in the relative abundance of 10 different compound groups were measured. A simultaneous decrease in relative abundance of lignin and polysaccharides during the initial composting phase indicates co-metabolism of lignin. So, while the presence of lignin is commonly regarded as a challenge in composting, it undergoes degradation through distinct mechanisms at the various composting stages. Subsequently, three mature rose-waste based composts were amended prior to seedling planting and either standard fertigation or halved fertigation was administered. Soil quality parameters, leaf nutrient levels and vase life were assessed regularly. Furthermore, yield of cut roses was tracked daily. After 12 months a significant increase of 8% yield in terms of harvested stems and kg's was observed except for the halved fertigation treatment, where this increase diminished after approximately 9 months, indicating depletion of easily available nutrients provided by the compost. Overall, this project provides actionable practices for rose waste management, promoting the re-use of valuable green waste and alleviating soil exhaustion in intensively used horticultural soils.

#### AGRICULTURAL SOILS INCREASING C STORAGE: MANURE-DERIVED BIOCHAR AND SPONTANEOUS VEGETATION, TWO VIABLE ALTERNATIVES IN A CLIMATE CHANGE SCENARIO

M. GINEBRA AGUILAR <sup>1</sup>, C. MUÑOZ <sup>2</sup>, E. ZAGAL <sup>2</sup>, L. BONJOUR <sup>1</sup>, M. ONTIVERO <sup>1</sup>, C. ACOSTA <sup>3</sup>, J. CANDELARIA <sup>4</sup>, E. MARTÍNEZ-CARRETERO <sup>1</sup>

<sup>1</sup> Instituto Argentino de Zonas Áridas (IADIZA), Grupo de Geobotánica y Fitogeografía., Mendoza, ARGENTINA

<sup>2</sup> Universidad de Concepción, Department of Soils and Natural Resources, Faculty of Agronomy, Chillan, CHILE

<sup>3</sup> Grupo AVINEA, Bodega Argento. Grupo vitivinícola, Mendoza, ARGENTINA

<sup>4</sup> Universidad Nacional de Cuyo, Cátedra de Edafología, Mendoza, ARGENTINA

Modern soil science faces the challenge of determining the most effective agricultural practices for increasing C storage in different scenarios, such as: varying goals (biodiversity, climate, agronomic), resource availability, and crop and soil conditions. While manure is commonly used to provide nutrients to soil and plants, it can have a priming effect on agricultural soils with high C content. The application of more stable amendments like manure-derived biochar may be a preferable alternative to enhance soil C storage, improve soil properties, and increase crop yield in Andisols in Chile. In arid regions of Argentina, vineyards are a significant crop planted in soil with very low C content, such as Entisols. The spontaneous vegetation that grows in vineyards can offer ecosystem benefits, including carbon storage (soil and biomass) and biodiversity enhancement. We aim to evaluate these two approaches for increasing C storage and their associated benefits in the agricultural soils of Chile and Argentina under field conditions. Our findings in Andisols in Chile indicate that the application of pig and dairy manure biochar after 6 months increased soil C storage (0-30 cm) with an average of 3.08 tC ha<sup>-1</sup>, and 0.9 t non-oxidizable C ha<sup>-1</sup>. These amendments also improved soil pH, nutrient availability, and Sorghum sudangrass yield with an average of 9 t ha<sup>-1</sup> compared to the unamended soil. On the other hand, not removing the spontaneous vegetation during 5 years in the inter-row of a Argentina vineyard increase 1.1 tC ha<sup>-1</sup> in the top-soil (0-30 cm) compared to uncovered soils. This vegetation contributed to aboveground and root biomass, storing between 0.57 to 2.79 tC ha<sup>-1</sup> per season. Additionally, its presence improved the biodiversity of the vineyard, (collection of new species of plants). Based on both studies, the use of manure-derived biochar and the preservation of spontaneous vegetation contribute to soil C storage and further agricultural soil targets, such as improved crop yields, increased fertility, and enhanced biodiversity.

#### EFFECTS OF STRAW-DERIVED ORGANIC AMENDMENTS ON SOIL AGGREGATION AND CARBON AND NITROGEN DISTRIBUTION IN BLACK SOIL

W. FAN, H.G. CAI, Y. LIANG, J.Y. YAN

Institute of Agricultural Environment and Resources, Jilin Academy of Agricultural Sciences, Changchun City, CHINA

In this study, we investigated the impact of maize straw return on the stability of black soil aggregates and the distribution of carbon and nitrogen. Soil samples from the plough layer (0-20 cm) were collected and treated with single chemical fertilizer (CK), chemical fertilizer combined with straw (ST), chemical fertilizer combined with compost (CP), and chemical fertilizer combined with biochar (BR). Results showed that compared to CK, the organic carbon content in soils treated with CP and BR increased significantly by 16.2% and 32.4%, respectively. Only the BR treatment showed a significant increase of 4.7% in soil total nitrogen content, resulting in the highest C/N ratio. The proportion of large aggregates (>0.25 mm) increased by 43.3%, 34.1%, and 22.9% in the ST, CP, and BR treatments, respectively, compared to CK. The mean weight diameter (MWD) of aggregates followed the order: ST>BR>CP>CK. Application of different organic materials increased the carbon content of aggregates in all size fractions, with the BR treatment showing the most significant increase (19.9%~65.8%), particularly in the 2~1 mm particle size fraction. The carbon-nitrogen ratio of aggregates in the BR treatment increased significantly (23.7%~41.5%). Biochar return increased soil organic carbon and total nitrogen content in the topsoil, while compost return significantly increased soil organic carbon content. The three organic material treatments resulted in the fixation of soil organic carbon in large aggregates. Biochar return also increased the C/N ratio of soil and aggregates, indicating enhanced biological stability of soil organic carbon.

<sup>6</sup> JAMSTEC, Yokohama, JAPAN

Soil is supporting sustainable food production with water, climate and nutrients in long-term. India is the largest rice exporter and rice-wheat cropping system in Northwest India has been established since green revolution, based on modern varieties and sufficient water and nutrients. However due to decrease of water availability and intensive continuous cropping, soil fertility and soil organic matter contents started to decline. Miss-managements of crop residues induce environmental problems such as straw burning, air pollutions and even human health.

We have developed India-Japan collaborative research project named Aakash (An interdisciplinary study toward clean air, public health and sustainable agriculture) to study sustainable straw management to reduce air pollution, such as assessing alternative crops rather than rice-wheat, smart straw managements including minimum tillage and biochar, monitoring straw burning by satellite and health conditions by small sensors and questionnaires.

In the international research project, there are 3 working groups (WG) and WG1 has started to examine 1) the effects of incentives aimed to promote behavioral changes on farmers from socioeconomic viewpoint and 2) the various alternatives from rice-wheat system to reduce burning straw from agronomic viewpoint. As for mitigation to reduce straw burning and greenhouse gases (GHGs: CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O) from field, crop residue should be managed properly, such as biochar. In LPU campus, we established field trial to investigate the effect of two kinds of biochar (made from rice husk and rice straw). During wheat cultivation, soil and gas were sampled to see seasonal changes in soil properties and emissions. Biochar reduced GHGs emissions and increased soil carbon, a co-benefit of reduction in air pollution and contribution to international efforts of GHG emission mitigation and sustainable agriculture.

#### EVALUATING CHANGES IN THERMAL STABILITY OF ORGANIC CARBON IN BIOCHAR-AMENDED SOILS DURING MICROBIAL INCUBATION

E.L. DEFRANG<sup>1</sup>, J. TRABUCO<sup>2</sup>, M. AEPPLI<sup>1</sup>

<sup>1</sup> EPFL Department of Civil and Environmental Engineering, SOIL Lab, Sion, SWITZERLAND

<sup>2</sup> YpHen SAS, Thonon-les-Bains, Auvergne-Rhône-Alpes, FRANCE

Biochar is an emerging solution to treat contaminated and degraded soils. However, it is unclear to what extent biochar plays a role in soil organic carbon (SOC) stabilization. Currently, there are a variety of methods to assess SOC stability in soil, including chemical fractionation, thermal analysis, and spectroscopy. Thermal analysis methods constitute a rapid, convenient alternative to conventional extraction methods, though their sensitivity to changes in SOC due to biochar soil amendments is unknown. It is therefore imperative to develop novel methodologies to provide a consistent basis to evaluate the effectiveness of different organic amendments on SOC stabilization.

In a laboratory experiment, we used Differential Scanning Calorimetry-Thermogravimetry (DSC-TG), to quantify thermal signature changes in biochar-amended soils. We tested biochar-based encapsulated soil amendments produced by our industry partner, YpHen, for use in in-situ bioremediation. These amendments are hypothesized to not only improve soil health, but also play a secondary role in increasing soil carbon stability by providing growth support for microbial communities that stabilize carbon. We thus investigated the impact that biochar-based capsule amendments have on thermal SOC stability during a 4-week incubation period of model soils inoculated with different microbial communities used in bioremediation projects. Additionally, nutrient sources were varied over the samples to represent both simple sugars and complex-molecule carbon systems. The goal of this experiment was multifold: to ascertain DSC-TG sensitivity to small fluctuations in SOC stability, to assess its suitability for gauging the dynamics of SOC stability in amended soils, and ultimately, to validate the efficacy of diverse soil amendment approaches in stabilizing SOC.

In my presentation, I will evaluate the propensity of DSC-TG to identify changes in SOC stabilization from biochar soil amendments. I will also discuss the effects of varied microbes and nutrient sources on carbon stability during incubation. Finally, I will discuss the role that biochar amendments may play in future remediation, not only for soil restoration, but as a driver of carbon stabilization.

#### LONG-TERM COMPOST-AMENDMENT INFLUENCE ON TOP- AND SUB-SOIL HYDROLOGY AND PHYSICAL RESILIENCE

K LOADES, D BOLDRIN, A BARCLAY, S CAUL

THE JAMES HUTTON INSTITUTE - ECOLOGICAL SCIENCES, DUNDEE, SCOTLAND, Dundee, UNITED KINGDOM

The application of composts to agricultural soil is a well-established practice with evidence showing multiple benefits. With soil health and function becoming increasingly important, as is the drive to increase soil carbon, it is critical to understand the impact of soil organic amendments on multiple functions within both top-soil and sub-soil.

A long-term compost application trial was established in 2004 under continuous spring barley with three differing compost application rates and an unamended control treatment. Plot structure is a randomised block design with soil being a sandy silt loam cultivated under minimum tillage practices. Following establishment in 2004 all treatments, except the control, received 50 t ha<sup>-1</sup> of municipal green compost, low (35 t ha<sup>-1</sup>), medium (100 t ha<sup>-1</sup>), and high (200 t ha<sup>-1</sup>), applications in 2006 and 2007 before continuous 35 t ha<sup>-1</sup> annual applications from 2008 to 2022. Intact soil cores were collected from both top-soils and sub-soils for each plot in spring 2022 prior to compost application and cultivation. In the laboratory, saturated hydraulic conductivity and water retention curves were tested. Additionally, soil resilience to loading (compaction) and water erosion (aggregate stability) were also assessed. Within top-soils, medium and high compost application rates increased hydraulic conductivity when compared to control plots. In contrast, the low compost application rate decreased hydraulic conductivity when compared to unamended plots. Surprisingly, within sub-soils, compost application was found to significantly impact hydraulic conductivity, with hydraulic conductivity shown to be highest within the medium rate compost application treatment. A significant difference in water stable aggregates within top-soils was observed between treatments. Bulk density decreased with increasing compost levels. Compost amended treatments highlighted greater resilience to loading (i.e., compaction) in both top- and sub-soils.

In conclusions, results show that the influence of compost surface application under minimum tillage practice is not limited to top-soil but can positively impact sub-soil physical properties.

Soil carbon (C) sequestration is a nature-based solution against global warming and helps to meet the targets of ensuring food supply, mitigating climate change, and sustaining biodiversity. Current projections suggest considerable warming and aridity trends in Mediterranean regions, where crops face a decline in crop yields and climate resilience. The loss of soil organic C (SOC) is enhanced in soils under arid conditions, a ubiquitous circumstance in Mediterranean climates. Also characteristic in arid soils is the accumulation of large quantities of soil inorganic C (SIC) in the form of CaCO<sub>3</sub>. Traditionally, SIC has been disregarded due to its geological time scale turnover. However, increasing evidence reveals that a relevant fraction of SIC links the long-term geological C cycle with the short-term biological C cycle. Not considering the inorganic C pool in calcareous soils may lead to inefficient strategies against global warming.

Compost and biochar amendments constitute advantageous strategies to increase soil C build-up and maintain soil fertility. However, their impact on SIC has been scarcely evaluated. In 2013 we initiated a long-term field experiment with amendments of compost, biochar, and their mixture (90:10) every two years in an organic olive tree crop. Over 10 years we have studied the accrual of SOC and SIC at several soil depths, the natural <sup>13</sup>C abundance in both soil C pools, and the nutritional and phytochemical assessment of the olive trees through yield monitoring and olive leaves analyses.

Our preliminary results show increased SOC accrual in compost and biochar-amended soils, and increased nutrient availability in compost and mixture treatments, even at 50 cm soil depth. Crop yield, nutritional status, and phenolic compounds in leaves have been similar in all the treatments. We expect that the results from <sup>δ13</sup>C changes in C pools at several soil layers will provide a deeper understanding of the links between SIC and SOC and facilitate more accurate estimations of the C sequestration potential of calcareous soils in arid climates.

Organic waste products (OWP) application and cover crops are agronomic levers to improve soil health. OWP can be valorized by anaerobic digestion to produce biogas. The chemical composition of digestate differs from that of its source material. Labile fraction being partly consumed by microorganisms, recalcitrant molecules accumulate in digestate. Studies on transfer of DOM (dissolved organic matter) towards the subsoil in soil receiving digestate are scarce. In a previous lysimeter study over 9 years, higher topsoil-DOC (dissolved organic carbon) concentrations under digestate were observed every year compared to its original slurry and associated with different winter crops, probably in relation to the root development of the crop. The extra-DOC could come from a higher production of root exudates due to a potential auxin effect of the digestate and/or a solubilization of the recalcitrant organic matter from digestate via the alkalinization of rhizosphere. To check this hypothesis, the evolution of DOM chemical composition after digestate application (i) associated with different winter crops, (ii) during the drainage season and (iii) between the topsoil and the subsoil was studied. Lysimeters at 40 cm (topsoil) and 90 cm (subsoil) depths were monitored in 2018-2019 (wheat) and 2020-2021 (mustard), from November to March under pig slurry (PS) and digestate from PS (PS-DIG). The DOM composition of lysimeters samples and water extracts from PS and PS-DIG (WEOM) were analyzed by thermochemolysis coupled to gas chromatography and mass spectrometry (THM-GC-MS). A higher proportion in phenols and dicarboxylic acids was measured in WEOM from PS-DIG compared to PS. Under mustard, the DOM composition of the PS-DIG modality at the beginning of the drainage season was close to the one of WEOM of PS-DIG. Under wheat, the DOM composition of the PS-DIG modality in the middle of the drainage season seemed only partly influenced by the PS-DIG application, with a higher proportion of dicarboxylic acids but no difference in phenols proportion compared to PS.

#### THE POTENTIAL OF NO-TILL AND COMPOST FOR MITIGATION OF SOC LOSS AND GHG EMISSIONS: LESSONS FROM THE LONG-TERM FIELD EXPERIMENT »TILLCOMP«

A. SCHWARZMANN, K. ELER, A. GOVEDNIK, K. OCVRK, M. SUHADOLC, R. MIHELIC

University of Ljubljana, Biotechnical Faculty, Ljubljana, SLOVENIA

The synergy of no-till and compost fertilization has a high potential for increasing soil organic carbon stocks (Corg) and diminishing greenhouse gas (GHG) emissions. Corg stocks and GHG emissions (N<sub>2</sub>O, CO<sub>2</sub> and CH<sub>4</sub>) were studied in a long-term field experiment »TillComp« in Ljubljana, Slovenia. The experiment was established in 1999 and it focuses on the effects of different fertilization treatments (no-fertilization control, compost fertilization, mineral fertilization) and tillage intensities: conventional plough tillage (CT) to a depth of 25-28 cm and non-inversion minimum tillage to a maximum of 10 cm depth which was replaced by a no-till system (NT) in 2017. Due to more than 20 years of the experiment, the differences in soil quality parameters between treatments are significant. In-situ measurements of GHG emissions were carried out with static chambers (Krauss et al., 2017) in 2021 and 2023, when maize was the main crop. The aim of this study was to evaluate the trade-offs between GHG emissions, Corg stocks and maize yields. We hypothesized that NT increases Corg stocks, but on the other hand poses risk for denitrification. We observed differences in Corg stocks in the top 20 cm of soil after 24 years of the experiment. In NT, Corg stocks are between 14,2 and 26,7 t Corg /ha higher than in CT. The highest Corg stocks are in the treatments fertilized with compost. CO<sub>2</sub> emissions were lower in both years on NT for all fertilization treatments, and N<sub>2</sub>O emissions likewise, except for mineral fertilization in short event after fertilizer application, where we measured significantly higher emissions compared to CT. Yield scaled emissions were generally higher with no-till compared to conventional tillage. Regarding fertilization in general, the control had higher yield scaled emissions compared to compost and mineral fertilizer, and compost performed better than mineral fertilizer on NT in 2023. We conclude that the higher Corg stocks in soils with NT do not lead to an increase in GHG emissions.

The application of amendment guarantees the management of soil fertility and carbon sequestration due to their effect on soil organic carbon (SOC). The project "HYDRORG" aims to study these interactions, starting from the organic fertiliser characterization. The hydrochar (HC) is produced from the hydrothermal carbonisation of organic wet waste and the post-treatment can improve its agro-environmental properties.

The HC (190° C for 2 h) was produced from winery and dairy agro-industrial sludges. The HC was compared to compost (COM) and MIX (obtained by mixing HC and compost, 1:1 w/w in an aerated pile). Besides the analysis of nutrients, pH, EC, TOC, the phytotoxicity and the effect on plant growth at increasing doses have been assessed. The effects were defined by incubating amended soil at 10 and 20 Mg/ha, 25°C, and 50% of WHC, for 1 and 12 months. The organic C was analysed by distinguished dissolved organic matter and the soil recalcitrant organic matter.

The MIX pile showed a decrease in oxygen uptake (from 1789 to 421 mgO<sub>2</sub>/kgVSh). HC has a high content of both TOC and TKN (47 and 4.8 g/kg). P content was different among products (47 g/kg HC, 4.5 g/kg COM, 12.9 g/kg MIX). The MIX had a lower pH value compared to others. MIX showed a phytostimulant effect compared to COM, while HC is phytotoxic. HC contained a greater content of aliphatic compounds than aromatic ones. After 1 month, the soil amended with MIX and HC showed an increase of P available at higher doses. The MIX amended pots reached higher nitrate content (from 25.0 to 54.6 mg/kg), while HC determined higher ammonia content at the beginning of incubation (17.6 mg/kg). TOC increased in both, HC and COM-amended pots compared to control, after 12 months.

The integrated knowledge of the amendments and their effects (chemical, on soil, GHG emission, etc.) can help to plan efficient and efficacy agronomic use and to better comprehend their environmental role.

The large quantities of waste from the meat industry represent one of the major environmental challenges facing the food industry today, due to their biological instability, rapid fermentation, and high level of potential pathogenic character. The advances in biochar production through slow pyrolysis by fixed bed reactor offer a sustainable option to exploit the benefits of animal bone waste characterized by high organic and inorganic content. This study aims to investigate the biochar produced from animal bone waste at different temperatures (500°C and 700°C), at 10 °C/min as heating rate, and 1h as a residence time. The main characteristics of the produced chars at different experimental conditions were evaluated in terms of proximate and ultimate analyses, thermogravimetric behavior, FTIR spectroscopy, X-ray diffraction, pH, Electrical Conductivity (EC) and surface morphology. A three months pot experiments in a greenhouse using the produced biochars was conducted at the rates of 0, 2 and 4 g. Kg<sup>-1</sup> soil. The experimental results revealed that the pyrolysis temperature have a significant effect on biochar yields. Thus, the maximum biochar yield was obtained at 500°C (around 55 wt.%). The obtained results showed that the biochar generated have a high Carbon content (~13 wt.%) for the biochar produced at 500°C and surface area (110 m<sup>2</sup>.g<sup>-1</sup>) for the biochar produced at 700°C and both biochars have a high ash content (more than 75 wt.%). The addition of ash-rich biochars increased the total phosphorus and calcium, total nitrogen, pH and EC values in the soil. However, there was a decrease in C/N ratios indicating the acceleration of mineralization of the treated soil. The change in soil properties increased with increasing biochar application doses. The results demonstrate the great potential of animal bone waste as a feedstock for the biochar production through slow pyrolysis, as well as its application as an amendment to clay loam soil.

This comprehensive study investigates the potential of ammonium (NH<sub>4</sub><sup>+</sup>)-enriched zeolite, using treated wastewater, as a soil amendment for wheat cultivation. The primary objective was to assess the impact of NH<sub>4</sub><sup>+</sup>-enriched zeolite on soil N dynamics and wheat growth, comparing its efficacy with a no-fertilizer control and standard inorganic fertilizer.

The study involved extensive experimentation, including the characterization of the NH<sub>4</sub><sup>+</sup>-enriched zeolites and assessing their influence on two different soil types with wheat as model crop. It provided valuable insights into the NH<sub>4</sub><sup>+</sup> desorption kinetics from the zeolites and examined the interaction between soil characteristics and zeolite application, particularly the influence of zeolite particle size on NH<sub>4</sub><sup>+</sup> release and soil improvement.

Key findings revealed that the application of NH<sub>4</sub><sup>+</sup>-enriched zeolites led to similar effects as inorganic fertilizers, enhancing nutrient availability and positively affecting plant growth and N accumulation. The ATR-FTIR analysis confirmed the presence of functional groups indicative of NH<sub>4</sub><sup>+</sup> enrichment in the zeolites. Notably, the zeolite with smaller particle size exhibited greater NH<sub>4</sub><sup>+</sup> desorption, and both zeolites tested showed identical kinetic desorption processes, fitting the bimodal pseudo-second order kinetic model. This model highlighted two distinct desorption mechanisms. The study observed no significant soil effect on mineral nitrogen forms, attributing variations in mineral N forms more to nitrogen supply and the interaction between soil and N-supply. Fertilization efficiency varied across treatments, with inorganic N showing the most substantial effect. β-glucosidase activity, an indicator of soil microbial activity, was primarily influenced by soil type and was higher following inorganic N application.

Furthermore, both NH<sub>4</sub><sup>+</sup>-enriched zeolites, were effective in enhancing nutrient availability and plant N uptake, showcasing their potential as viable alternatives to conventional mineral fertilizers. The study concludes that NH<sub>4</sub><sup>+</sup>-enriched zeolites, due to their effective N provision, hold promise for sustainable agriculture, emphasizing the importance of further research in optimizing their use for different crops and soil types in a circular economy perspective.

The reuse of food wastes or agroindustrial by-products as soil amendments has been frequently reported for an effective control of several phytoparasitic nematodes, also including root-knot species of genus *Meloidogyne*, as well as for an improvement of soil quality and crop yield. The aim of this study was to assess the effects of spent coffee ground (SCG), brewer's spent grain (BSG) and wasted bread (WB), either raw or bioprocessed, with lactic acid bacteria (LAB) or a compost tea (CT), on the infestation of the root-knot nematode *Meloidogyne incognita* on tomato. Spent coffee ground, raw or bioprocessed with a CT extracted from a mature green waste compost, and BSG or WB, raw or bioprocessed with LAB strains, were incorporated to the soil at doses corresponding to 3000 kg ha<sup>-1</sup> organic carbon. All the amendments significantly suppressed the multiplication of *M. incognita* and gall formation on tomato roots as well as significantly increased plant growth. Bioprocessing SCG and BSG with CT and LAB, respectively, significantly improved the suppressiveness of raw materials to *M. incognita*, while only LAB-processed BSG significantly increased plant growth compared to the raw material. Results from this study indicated that the recovery of the three tested waste materials as soil amendments can provide an additional tool for a sustainable management of root-knot nematodes.

Soil quality decline represents a significant constraint on the productivity and sustainability of agriculture in the dryland regions. This study investigated the effects of compost and its mixture with biochar on soil fertility and barley yield in a typical Mediterranean sandy soil. In this context our research was carried out at the experimental field station of the Arid Regions Institute, located in southeastern Tunisia. Treatments were : control (T), 56 t ha<sup>-1</sup> compost (C), 10 t ha<sup>-1</sup> biochar + 56 t ha<sup>-1</sup> compost (B+C), 10 t ha<sup>-1</sup> biochar + inorganic fertilizer (B+F) and inorganic fertilizer only (F). At harvest time, plant samples and soils were collected for laboratory analyses. Results showed greater TOC and P under the treatment combination of (B+C) compared to control by 51 and 64%, respectively. Whereas application of biochar in combination with inorganic fertilizer resulted in a significant elevation of soil total nitrogen to 50 % as compared to control. B+C was the most efficient in improving aggregate stability (average improvement of + 48%). Several barley growth and yield parameters are significantly higher for (B+C) and (B+F) treatments. (B+C) significantly increased the grain yield by 30%. Almost all of the studied traits (leaf Chlorophyll content and leaf relative water content) were significantly affected by the application of these treatments. Indeed, B+C significantly increased the leaf chlorophyll content of barley by 13%. Also, it had a positive impact on leaf relative water content compared to the control treatment, with improving rate of 30%. Under the experimental conditions described in this study, biochar mixed with compost could be selected as the most suitable amendment for improving soil fertility and barley productivity.

#### LONG-TERM EFFECTS OF COMPOST ON SOIL HEALTH AND YIELD OF WINTER WHEAT IN SEMI-ARID ENVIRONMENTS

J. REEVE, I. ATOLOYE, A. JACOBSON, M. YOST, E. CREECH

Utah State University, Logan, USA

Dryland wheat (*Triticum aestivum* L.) is an important crop in Utah and the Intermountain Western United States. Yields are often severely constrained by lack of rainfall and, to mitigate crop failure, a wheat-fallow system is used. Organic dryland wheat-fallow systems risk major soil loss due to dependency on tillage and use of organic inputs is generally not cost-effective in the short-term. The objective of this study was to assess the long-term effects of a one-time compost application on soil health and organic carbon (OC) content. Compost made from cattle manure and straw was applied once to a dryland organic winter wheat (*Triticum aestivum*)-fallow (WW-F) system at 50 Mg ha<sup>-1</sup> dry weight in 1994 in a randomized complete block design with three replicates. Soil samples were collected at 0-10, 10-30 and 30-60 cm and OC of bulk soil, particulate organic matter (POM), sand associated organic matter (SMA), silt + clay mineral associated organic matter (MAOM) and dissolved organic carbon (DOC) were measured. Active carbon, microbial biomass, enzyme activities, aggregate stability and soil nutrients were measured on the 0-10 cm depth, and grain yield was collected. Twenty-eight years later, yields in compost plots (1.4 Mg ha<sup>-1</sup>) remained significantly higher ( $P < 0.05$ ) than in control plots (0.78 Mg ha<sup>-1</sup>). Plant-available phosphorus, acid phosphatase activity, and total nitrogen were 143%, 37%, and 29%, greater respectively. Soil organic carbon (SOC) and aggregate stability (SLAKES) were 25% and 143% ( $P < 0.1$ ) greater compared to the control while POM and MAOM were greater in surface soils. Since the compost was applied, yields at the site are increasingly constrained by lack of precipitation, but 38% of yield variability was explained by soil OC content, while soil phosphorus availability and soil respiration were also significant contributors to yield fluctuations. Infrequent applications of compost to dryland wheat not only improve soil health but could also provide increased resilience to climate change.

#### CARBON STOCK AND GREENHOUSE GAS EMISSIONS IN TIDAL MARSHES ALONG THE WHITE SEA COAST

P. KRASILNIKOV, I. BAGDASAROV, A. BOBRIK, I. ILICHEV, G. KAZHUKALO, S. OGORODOV, M. TSEITS

M.V. Lomonosov Moscow State University, Moscow, RUSSIA

During field work in late July – early August 2023, a soil-botanical and geomorphological survey of the tidal zone south of the village of Kolezhma located on the Pomor coast of the White Sea was carried out. The study area was located in coniferous forest (taiga) zone with the Dfc climate: the mean annual temperature was 1°C and annual precipitation 435 mm. Halophytic species dominated in the vegetative cover at low marshes: *Juncus gerardii* L., *Salicornia europaea* L., *Carex salina* Wahlenb., *Bolboschoenus maritimus* L., *Puccinellia coarctata* Parl., and *Eleocharis uniglumis* Link. High marshes were occupied with zonal grassland species. The soils were classified as Tidalic Fluvisols, Fluvic Stagnosola and Fluvic Gleysols. On average, soil carbon reserves for the study plot amounted to  $71.4 \pm 38.2$  Mg C·ha<sup>-1</sup>, and the average reserves of plant C equaled  $3.95 \pm 2.42$  Mg C·ha<sup>-1</sup>. We found that the emission of carbon dioxide by soils of marsh ecosystems varied widely from 0 to 122 mgCO<sub>2</sub>·m<sup>-2</sup>·h<sup>-1</sup> and averaged  $31 \pm 41$  mgCO<sub>2</sub>·m<sup>-2</sup>·h<sup>-1</sup>. This indicator was characterized by high spatial variability: the coefficient of variation was 134%. The distribution of CO<sub>2</sub> emission values was asymmetric, the median was shifted towards low values. The high variability in the values of carbon dioxide emissions by soils was due to both the peculiarities of the vegetation cover and the varying moisture content of various sections of marsh ecosystems. In general, the soils of the watters and low marshes are characterized by low CO<sub>2</sub> emissions. The soils of the high marshes and the marine terrace do not differ statistically significantly in CO<sub>2</sub> emissions. The analysis of data on CO<sub>2</sub> emissions from the soils of marshes of the Pomor coast of the White Sea indicates mainly their high spatial variability that should be considered in estimates of greenhouse gas fluxes in the coastal areas.

##### THE DYNAMICS OF ORGANIC CARBON AT THE SOIL-BEDROCK INTERFACE

D. EVANS

Cranfield University, Cranfield, UNITED KINGDOM

Recent research has revealed the size of the subsoil organic carbon (OC) pool and the mechanisms by which OC is transported to, and incorporated within, subsoils. Despite this, there remains almost no research into the OC pool within soil parent materials underlying soil profiles. Achieving Net Zero carbon relies on us accounting for all carbon pools and sequestration processes in soil profiles, including those that take place across the soil parent material-soil interface, particularly during bedrock weathering and soil formation processes. In this contribution, I will present the findings from one of the first studies globally to examine the role of soil parent materials in storing OC. Thermogravimetric analysis was used to measure the OC content in soils and their underlying SPMs across a variety of land use contexts, and to assess the relative stability (or persistence) of this OC pool. Initial findings demonstrate comparatively large OC stocks in soil parent materials, and I explore potential mechanisms for this. Such a finding extends an ongoing discussion about the role of deep soil horizons in carbon sequestration and could lead to new and innovative approaches for tackling Net Zero. However, some soil parent materials represent large sources of petrogenic (rock-derived) OC which, during soil formation, could become oxidised by microbial communities. Here, I will present some exciting preliminary respiration flux data from protosoils developing over recently exposed carbon-rich bedrock (shale) in the Swiss Alps. Petrogenic OC from soil parent material represents a missing source of OC for the majority of, if not all, soil OC models. Accounting for these inputs is crucial as we improve our understanding and modelling of soil OC over the next century.

<sup>2</sup> University of Copenhagen, Copenhagen, DENMARK

<sup>3</sup> University of Amsterdam, Amsterdam, THE NETHERLANDS

Restoring biodiversity and ecosystem services in forest ecosystems is a primary focus of the UN Decade on Ecosystem Restoration. The vitality of such forests relies strongly on the intricate dynamics of carbon and nutrient cycling within their soils. However, our understanding of how to strategically manage soil carbon dynamics in forests remains limited. While tree species selection based on litter quality has proven effective in rehabilitating degraded soils and enhancing forest health in some instances, similar efforts in other locations yield inconsequential or even counterproductive results. To advance our comprehension of the contextual factors influencing such outcomes, a deeper understanding of the underlying mechanisms is therefore imperative.

In this contribution, we synthesize a decade's worth of research on acidified forest soils in Europe, encompassing both detailed case studies and extensive European datasets. Our argument posits that the effects of litter and tree species on soil carbon dynamics should be perceived as a nuanced interplay involving tree species, soil fauna, micro-organisms, organic matter composition, soil mineralogy, and soil anisotropy. Furthermore, our findings illustrate that biota, specifically trees and soil fauna, can drive the mechanisms of carbon sequestration and stabilization, as well as nutrient cycling in forest soils, by establishing feedback loops among various components of the soil carbon cycle. Importantly, these feedback loops are limited in space and time, being most pronounced near the tipping points between different geochemical soil process domains. Enhanced understanding of when and where these feedback loops occur serves as a crucial avenue for forest managers to prioritize interventions where they are most likely to yield a positive impact. Additionally, it underscores the perils of consolidating soil carbon data in broad meta-analyses without adequately considering variability and diversity in the soil system.

Salt-affected soils and limited availability of freshwater for irrigation are global problems, which are increasing due to climate change. Soil salinity becomes problematic once the concentration of soluble ions negatively affects soil functions and crop development. While the effects of salinity on soil properties have been described in arid and semi-arid regions, its effects on soils in temperate regions and on soil microbes, is poorly characterized. One novel strategy to mitigate the effects of soil salinity is being investigated by SoilSalAdapt project: this is testing the hypothesis that soil microbiome adapts to gradually increasing saline irrigation, which may improve crop tolerance. In order to achieve sustainable farming systems and maintain productivity and soil health, it is crucial to understand the short and long-term impacts of saline irrigation. These impacts can be studied by modelling soil salinity and soil water content and simulating multiple scenarios, considering different irrigation strategies and projected climate change conditions.

Models of soil salinity and soil water content were developed from an experiment to empirically test this hypothesis. In this experiment, spinach was grown in 30 L pots across three different soils (two sandy loams and one loam) inside a polytunnel. Spinach was irrigated with freshwater and, at the end of the growing cycle, with highly-saline water (9 dSm<sup>-1</sup>), to simulate limited availability of freshwater at this stage. The crop evapotranspiration in standard conditions was obtained with the dual crop coefficient approach, using the software application SIMDualKc. The evaporation and transpiration were used as inputs for HYDRUS-1D, to model soil salinity (electrical conductivity of soil water) and soil water content, integrating the water and salinity stresses during the spinach development. The resulting models for the three soil types have a root mean square error between 1.74 and 3.31 dSm<sup>-1</sup> for soil salinity and between 0.024 and 0.063 cm<sup>3</sup>cm<sup>-3</sup> for soil water content.

#### EFFECTS OF COMPOST MADE FROM COMPOSTABLE BIOPLASTIC PACKAGING ADDED TO ORGANIC WASTE ON WHEAT HEALTH AND RHIZOSPHERE MICROBIOME: A FIELD EXPERIMENT

A. LA TERZA<sup>1</sup>, M. COLETTA<sup>1</sup>, A. D'ALESSANDRO<sup>1</sup>, G. SAGRATINI<sup>2</sup>

<sup>1</sup> University of Camerino, School of Biosciences and Veterinary Medicine,, Camerino, ITALY

There is a growing global demand for innovative and sustainable bioplastic packaging to reduce the use of petroleum-based plastics. In line with the principle of a circular bioeconomy, the use of compostable bioplastics (BPs) can bring several benefits to composting and urban organic waste (UOW) management by reducing contamination with conventional plastics and enabling the production of compost that can be safely used in agriculture. However, the potential impact of the presence of BPs in compost on the soil microbiome and plant health needs to be assessed.

This study aimed to evaluate and compare the effects of 'standard' compost (Com) obtained from UOW and UOW composted with 3% BPs (Mater-bi) (BioP) on the health of wheat and its rhizosphere microbiome. Composting was carried out in a industrial composting plant under the supervision of the Consorzio Italiano Compostatori (CIC). In 2021-2022, field trials were carried out at an agricultural experimental station. Three treatments (Com, BioP and Ctrl) were tested with five replicates each. At the time of flowering, ten plants and the associated rhizospheric soils were collected from each plots. Morphological and productive wheat traits were measured. Bacterial and fungal communities were analysed by 16S and ITS metabarcoding.

No significant differences between treatments were found for wheat traits. However, Com and BioP compost addition significantly changed the microbial communities compared to the Ctrl, although few taxonomic and functional differences were observed between the Com and BioP communities. However, network analysis revealed significant differences between these communities, with BioP showing a much more connected community compared to those of Com and Ctrl. Furthermore, the addition of compost, regardless of type, was able to select beneficial taxa involved in nutrient cycling and plant growth promotion.

The results showed that adding BPs did not negatively affect the quality of the compost, neither the wheat nor the health of the soil microbiome. Thus, BPs may represent a valid and sustainable alternative to conventional plastics.

##### LONG-TERM AGRONOMIC LAND MANAGEMENT SHAPES SOIL MICROBIOME BIODIVERSITY AND FUNCTION

M. CHOUDOIR<sup>1</sup>, M. SERRANO PEREZ<sup>1</sup>, A. BREISTER<sup>1</sup>, A. PERALTA<sup>2</sup>, A. WOODLEY<sup>3</sup>

Global land use change, primarily agricultural intensification and abandonment coupled with climate change, threatens soil biodiversity and beneficial soil functions. Soil conservation is critical for ensuring sustainable food production under future climate scenarios. However, we lack a robust framework to predict how environmental and land use changes shape soil microbiome structure-function relationships. While microbial communities are intrinsically dynamic, long-term experiments provide invaluable insights into the cascading effects of microbiome environmental responses on ecosystem-level functionality. The Center for Environmental Farming Systems (CEFS) Cherry Research Farm (Goldsboro, NC, USA) is a large-scale (over 200 acres) research station located in the Mid-Atlantic United States. The CEFS Farming Systems Research Unit (FSRU) is a multi-decade agricultural experiment of replicated systems with varied tillage, cover crops, and cropping systems that have been managed continuously since 1999. FSRU cropping systems include organic management, conventional best practices, integrated livestock, and successional or agricultural abandonment. We used amplicon surveys targeting 16S rRNA genes, ITS, and 18S rRNA genes for characterizing bacterial, fungal, and eukaryotic microbial communities, respectively. We generated this comprehensive microbiome dataset from archived soils sampled in 1999, 2015, and 2023 representing 0, 16, and 24 years of continuous land management. Preliminary amplicon data indicates that long-term management regimes shape community taxonomic structure, with successional plots demonstrating consistent variation compared to agricultural use plots. While community composition varies across system replicates, land use is the strongest predictor of microbiome beta-diversity. Here, we summarize results within the context of soil carbon dynamics. Next, we simulated an extreme weather event (i.e., flooding) and measured greenhouse gas fluxes across soil mesocosms representing different land use treatments. From this experiment, we used shotgun metagenomics to link functional gene potential with ecosystem function and resilience. Understanding how decades of agricultural land management impact soil microbiome structure-function relationships enhances our capacity to engage in sustainable agronomic land stewardship that supports climate-resilient food systems and global food security.

**IMPROVING SOIL ECOSYSTEM SERVICES THRU MULTIDISCIPLINARY FRAMEWORK THAT PROVIDES METHODS FOR NATIVE TREE PLANTING & GRASS BIOSWALES WITH FUNGI AMENDMENTS TO INCREASE SUSTAINABILITY & PHYTOREMEDIATION**

D. JANUARY-BEVERS, L. HOPKINS

Rice University, Houston, USA

Through a multi-partner, large-scale targeted native trees and grasses framework, implemented in the Greater Houston Region (Texas, USA), thousands of high-ranking tree species, prioritized based on their respective levels of GHG and water absorption and carbon sequestration, are being planted in locations that experience substantial flooding, have high rates of health effects exacerbated by air and water pollution and experience multiple days of elevated heat, and/or effects of sea level rise. The region's clay-rich soil composition, made up largely of vertisols and alfisols, influence watershed infiltration and non-point source runoff, especially during heavy rain events, and affect environmental enhancement and recovery efforts due to the dynamics of various heavily commercial industries that intersect with riverine systems and coastal wetlands. Regional programs that effectively provide large-scale conservation models and accompanying tools are discussed, including the Houston Ship Channel Trees Program and Riparian Targeted Use of Buyouts (TUBs) Program – providing thousands of targeted large-scale tree species on industrial properties along the 25 miles of the Houston Ship Channel, and prioritizing federally-qualified contiguous buyout properties adjacent to riparian corridors leading to Galveston Bay, and providing ecosystem services through large-scale targeted native tree plantings and creation of native grass bioswales on the recovered green spaces. These regional efforts are accompanied with fungi amendments with data analysis to provide baseline improvements in soil ecosystem services and illustrate benefit relevant indicators of increase sustainability and phytoremediation. The multidisciplinary framework includes engagement of multisectoral leadership broadened beyond those traditionally working on climate change resilience – including health departments, major energy and gas companies and native tree and grass growers, and community leadership. Aspects of the multidisciplinary framework can also be found in Plants, People, Planet A simple tree planting framework to improve climate, air pollution, health, and urban heat in vulnerable locations using non-traditional partners (<https://doi.org/10.1002/ppp3.10245>).

#### **INSIGHTS INTO THE EFFECTS OF LONG-TERM FERTILIZATION TREATMENTS ON MICROBIAL DIVERSITY OF BLACK SOIL**

S. WANG

Heilongjiang Academy of Black Soil Conservation and Utilization, Harbin, CHINA

##### 1. Background

Black soil areas of Northeast is the most important commodity grain base in China. However, its health has been compromised due to prolonged, improper fertilization practices. Soil microbial communities are vital for maintaining soil health, but continuous fertilization has altered the diversity of microorganisms in black soil, potentially affecting its functionality, and even threaten the soil health.

##### 2. Materials and methods

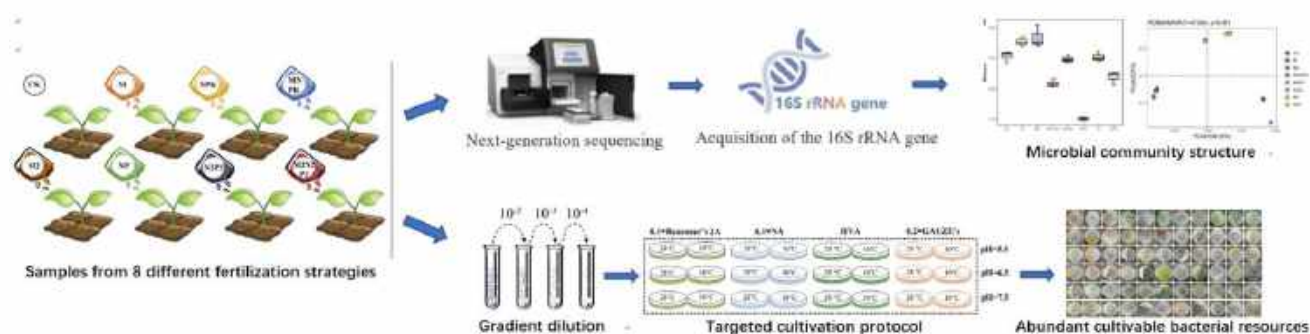

Methods for microbial studies of soil samples from eight long-term different fertilization are presented in Figure 1.

##### 3. Result

The compositional differences in microbial communities under all treatments are shown in Figure 2. Group CK-M-M2 exhibited similarity in bacterial communities, while the singly fertilized group NP-NPK-MNPK also showed similarities. The double fertilized group N2P2-M2N2P2 displayed a distinct bacterial community composition. Compared to the CK-M-M2 and NP-NPK-MNPK groups, the N2P2-M2N2P2 group exhibited a significant increase in network nodes, edges, average clustering coefficient, and network density (Fig. 3). Long-term different fertilization caused changes in soil physicochemical properties properties, which in turn affected the bacterial community structure, as shown in Figure 4, soil salinity, available phosphorus and available nitrogen are the key factors affecting microbial community composition in black soil. We cultured bacteria from samples using four targeted culture media, resulting in 2000 pure bacterial isolates. Taxonomically, these isolates were classified into five phyla, nine classes and 116 genera. Figure 5 illustrates the phylum level community composition of these cultivable bacteria.

##### 4. Conclusion

Long-term different fertilization have altered the properties of black soil, resulting in significant variations in the microbial community structures among samples. Our analysis grouped the 8 different fertilization treatment samples into three categories based on microbial community composition similarities: CK-M-M2, NP NPK-MNPK, and N2P2-M2N2P2. Notably, the N2P2-M2N2P2 group exhibited the most complex co-occurrence network. Furthermore, we isolated numerous pure bacterial strains from black soil, laying the foundation for further research on the functional aspects of black soil bacteria at the pure culture level.

#### EXPLORING SOIL MICROBIAL DIVERSITY IN THE ANDES-AMAZON TRANSITION ZONE: CONSEQUENCES OF CONVERTING FORESTS TO PASTURELAND

F.A. ORTIZ MOREA <sup>1</sup>, A.I. PEÑA GÓMEZ <sup>1</sup>, L.X. NUÑEZ RODRIGUEZ <sup>1</sup>, A.P. DE ARAUJO PEREIRA <sup>4</sup>, D.A. MORA MOTTA <sup>1</sup>, J.C. SUAREZ SALAZAR <sup>1</sup>, A.M. SILVA OLAYA <sup>1</sup>

<sup>4</sup> Universidade Federal do Ceará, Ceará, BRAZIL

Soil microorganisms play a pivotal role in ecosystem functioning, performing a range of essential functions. However, their resilience is tested by disturbances, primarily driven by changes in land use. The Andes-Amazon transition zone, known for its ecological significance, is under increasing pressure due to the conversion of native forests into pasturelands. While efforts to characterize biodiversity in this region have been on the rise in recent decades, our understanding of soil microbial communities and their responses to land use changes remains limited. In this study, we employed a shotgun DNA metagenomic sequencing approach to explore the composition, diversity, and functions of soil bacterial communities in both the litter layer and topsoil (0-10 cm) of a forest located in the Andes-Amazon transition zone in Colombia. Additionally, We evaluate how microbial soil communities are impacted by the establishment of pastures. Our results revealed that the forest litter harbors a distinct microbial ecosystem, characterized by the highest bacterial richness and diversity. This layer was also positively associated with increased carbon (C), nitrogen (N), and phosphorus (P) availability, as well as enzymatic activity linked to the mineralization of these elements. The transition from forest to pasture brought about significant alterations in the microbial community structure, accompanied by a reduction in soil acidity. Proteobacteria, Acidobacteria, and Actinobacteria were the most abundant phyla in all environments, with a predominance of Proteobacteria and Bacteroidetes in the forest litter. In contrast, the conversion from forest to pasture increased the abundance of Verrucomicrobia and Firmicutes in the soil. Functional profiles were most pronounced in the litter layer, followed by pasture and forest soils. These findings establish a fundamental framework for understanding the microbiome in the Andes-Amazon transition zone and its role in ecosystem functioning. Furthermore, this study sheds light on the consequences of land use changes on microbial communities.

#### VIRAL MODULATION OF SULFUR METABOLISM IN ACID SULFATE SOILS: UNRAVELING THE IMPACT OF VIRUSES ON SOIL BIOCHEMISTRY

H. HU, L. BI, J. HE

School of Agriculture, Food and Ecosystem Sciences, The University of Melbourne, Melbourne, AUSTRALIA

Acid sulfate soils cover extensive areas across the globe and pose profound ecological and economic challenges. While microbial activities associated with sulfur metabolisms primarily mediate the formation process of acid sulfate soils, the potential impact of viruses, known for their roles in infecting key microorganisms or encoding auxiliary metabolic genes (AMGs), remains largely unexplored. Here, we characterized the community and biogeochemical impacts of viruses in unoxidized acid sulfate soils (Hypersulfidic soils, pH 6.5-7.3) and oxidized acid sulfate soils (Sulfuric soils, pH < 3.3) using paired viromes and total metagenomes. Our results revealed higher diversity and distinct community composition of viral community in Hypersulfidic soils compared to Sulfuric soils. We identified much higher abundance and diversity of viral-encoded AMGs in Hypersulfidic soils than in Sulfuric soils. Particularly, those AMGs associated with assimilatory and dissimilatory sulfate reduction, organosulfur compound degradation, organic matter degradation, and electron transfer strongly implied the potential role of viruses in regulating sulfur cycling and shaping the formation of sulfidic materials in Hypersulfidic soils. The virus-host predictions linked viruses to a wide range of sulfate reducing and oxidizing microorganisms in both soil types, suggesting that viruses exerted a potential influence on the sulfur cycling processes via infection. Altogether, our findings highlight the roles of viruses in mediating sulfur cycling processes in acid sulfate soils and the potential of harnessing soil viruses for manipulating sulfur cycling microorganisms to control acid generation and mitigate soil acidity in practice.

<sup>2</sup> Department of Environmental Science, Policy and Management, University of California, Berkeley, Berkeley, USA

Aluminum (Al) toxicity impedes crop growth in acidic soils and is considered the second largest abiotic stress after drought for crops worldwide. Despite remarkable progress in leveraging the genetic diversity of plants for Al resistance, it is still unknown whether and how the microbiota confers Al resistance to crops. We found that a synthetic community (SynCom) composed of highly Al-resistant bacterial strains isolated from the rice rhizosphere increased rice yield by 26.36% in acidic fields. SynCom harvested rhizodeposited carbon for successful proliferation and mitigated soil acidification and Al toxicity through extracellular protonation. The functional coordination between plants and microbes offers a promising way to increase the usage of legacy phosphorus in topsoil. These findings highlight the microbiota–root feedback involved in crop abiotic resistance and the potential of microbial tools for advancing sustainable agriculture in acidic soils.

##### A COMPARISON OF EL-FAME, PLFA AND QPCR METHODS TO DETECT QUICK CHANGES IN SOIL BACTERIAL AND FUNGAL ABUNDANCE

J.A. SILES, R. GÓMEZ-PÉREZ, A. VERA, C. GARCÍA, F. BASTIDA

Department of Soil and Water Conservation and Organic Waste Management, CEBAS-CSIC, Murcia, SPAIN

Abundance is a key property of soil bacterial and fungal communities, which determines their functionality and their ability to respond to environmental changes. The quantification of fatty acids or marker genes are common methods to assess soil bacterial and fungal biomass. The analysis of soil fatty acids can be conducted via ester-linked fatty acid methyl ester (EL-FAME) or phospholipid fatty acid (PLFA) methods. Quantitative PCR (qPCR) can be used to quantify soil bacterial 16S rRNA and fungal 18S rRNA genes. The sensitivity of these approaches to detect increasing or decreasing microbial abundances in the short term is not well known. Therefore, this study compared PLFA, EL-FAME and qPCR methods to distinguish changes in bacterial and fungal abundances induced by the addition of antibiotics and antifungals (to induce decreasing abundances) and nutrients (to favor microbial proliferation) to soil from badland, agricultural and forest ecosystems after 2, 7, 14 and 28 days of incubation. Changing bacterial and fungal abundances measured through the three methods were also related to the soil microbial basal respiration to identify the approach targeting better the soil living microorganisms. The rates of microbial inhibition and proliferation induced by antibiotics and nutrients, respectively, varied between methods. In the three soil types, the PLFA approach detected the greatest decreasing rates of bacterial and fungal abundances generated by antimicrobials, especially in the very short term. Instead, the highest rates of bacterial and fungal proliferation induced by nutrient addition were detected by EL-FAME and qPCR. The results obtained with the three methods were highly positively correlated, but the correlation was higher between EL-FAME and PLFA for both bacteria and fungi. The bacterial and fungal abundances measured by EL-FAME across the experiment correlated better with soil basal respiration than those measured by PLFA and qPCR. The results from the present study and the lower cost and simpler methodology postulate EL-FAME as a more advantageous method than PLFA and qPCR.

<sup>4</sup> Universität Innsbruck, Department of Ecology, Innsbruck, AUSTRIA

Soil is referred to as a complex ecosystem, also comprising individual biological entities that harbor microorganisms. Traditional perspectives often examine soil microbial diversity as separate from those of the organisms that inhabit it. Here, we seek to challenge such view and propose an alternative and holistic interpretative framework in which the soil meta-community is the sum of different microbial communities belonging to various organisms found within the soil or interacting with it.

Applying this comprehensive view, this study explores soil prokaryote and fungal diversity and associated microbiota in mammals, invertebrates, and plants in alpine pastures. The study comprises more than 900 samples of soil (Ah horizon), rhizosphere (*Carex* spp. and *Festuca* spp.), invertebrates (nematodes, collembolans, earthworms, and beetles) and vertebrates (fecal eDNA of hares, wild ungulates and livestock) along an elevational gradient (which was used as a proxy for climate change) in the European Alps.

We found that, in addition to climatic and soil properties, biotic factors, especially the presence of living organisms like animals and plants, significantly shape soil microbial diversity. Analyses of fungal and bacterial taxa shared between sample types established greater overlaps between soil, rhizosphere, and soil-dwelling invertebrates, compared to other invertebrates and vertebrates. This finding highlights the central role of soil microbiota and the above/belowground and host/habitat-specific associations in the alpine meta-community. Our data reveal the similarity of microbial communities from different organisms interacting with the soil and underline their intricate connections in alpine pastures, even across a 1500 m elevation gradient.

The soil microbiome is an essential component of soil health that can provide multiple ecosystem services. However, anthropogenic disturbances such as contamination by trace elements and soil acidification could neglect microbial communities and their functions. Contrastingly, plants could safeguard the soil microbiome in contaminated conditions. This complex interaction occurs in the Puchuncaví Valley, a Mediterranean landscape of Central Chile impacted by an Industrial Complex. Although vegetation has been clearly affected here, *Baccharis linearis* (BL), a survivor plant, is prevalent even in the most contaminated areas. We hypothesized that contamination would affect the soil microbiome, but such an effect would be different in bulk soils versus soils surrounding roots of BL. We studied a contamination gradient: UC, MC, and HC (uncontaminated, moderately contaminated, and highly contaminated areas, respectively). In each area, we collected ten samples of bulk soil (BS; at least 1 m without vegetation) and ten samples of soil surrounding roots (SSR) of BL. Our contamination gradient (UC->MC->HC) showed soil acidification only in bulk soils while decreased soil organic matter content and increased copper concentration in both sample types. The bacterial richness was lower in the HC-BS compared to other BS conditions. In contrast, fungal richness did not show significant changes. Microbial communities showed that community similarity between BS and SSR decreases as the contamination increases. This disruption was evident in the compositional analyses. Bacterial Families were shaped by the sample rather than the contamination degree, while both factors were significant for fungi. Network analyses unveiled that the higher the contamination, the less the microbial co-occurrence. Our functional analysis revealed that contamination drastically impacts biogeochemical cycling, by decreasing soil organic matter and decomposing microorganisms. Moreover, we observed that the higher the contamination, the higher the abundance of human disease-associated microbes, but plants reduced this hazard. This final result supports the postulates of one health because the survivor BL plant promotes healthier soil fostering overall environmental well-being for ecosystems and people.

Understanding the soil and environmental controls of microbial functional diversity is required to determine the consequences of future climatic conditions and land use pressures. Simply counting and categorizing soil microbes based on taxonomy does not reveal their functional roles. We need to delve into functional diversity to understand the relationship between biodiversity and ecosystem functions. This concept captures the various functions that organisms perform within ecosystems. We aimed to explore the influence of soil and environmental variables on alpha-diversity and functional diversity of bacterial communities in Danish soils.

We collected over 7000 topsoil samples from natural and agricultural areas across Denmark. Soil samples were analyzed for their bacterial composition through a DNA metabarcoding approach. From the DNA sequences, an operational taxonomic unit (OTU) table was generated, and the taxonomical information was assigned. We calculated alpha-diversity and we used the FAPROTAX (Functional Annotation of Prokaryotic Taxa) database to associate potential functions to bacterial OTUs. We utilized spatial layers of soil properties, climate, vegetation, geomorphology, and parent materials to explain both the alpha-diversity and the potential functions of bacterial communities related to N cycling.

Diversity was higher in natural soil than in human-modified environments as well as the abundance of OTUs potentially performing nitrogen fixation. However, abundance of bacteria potentially involved in nitrification and ammonia aerobic reduction was higher in agricultural soils. Interactions among the explanatory variables best explained spatial patterns of bacterial community diversity and predicted functions. We consider that taxonomical and functional diversity should be studied simultaneously for monitoring purposes as functional diversity influences ecosystem functioning, services provision, and soil health.

#### TEMPERATURE TOLERANCE AND RESPONSE TO CHARCOAL APPLICATION OF ARBUSCULAR MYCORRHIZAL FUNGI FROM AN AGROECOSYSTEM IN THE ARABIAN DESERT

A.ALAM, E NEUMANN

ASPIRE Research Institute of Food Security in Drylands, CAVM, United Arab Emirates University, 15551, Al Ain, UNITED ARAB EMIRATES

Arbuscular mycorrhizal fungi have been shown to support the nutrition of their host plants on soils with poor availability of nutritional elements. Though natural vegetation is very sparse in the deserts of the Emirate of Abu Dhabi, AM fungal root colonization is commonly observed in agricultural plants. So far, very little is known about the origin of these AM fungi, their physiological properties, and their responses to management practices. In the first experiment, topsoil material from an agricultural field in Abu Dhabi was used for inoculation of *Sorghum bicolor* plants grown in sterilized dune sand either or not amended with a 2 % volume of charcoal. Though the sampled field had been left fallow for six months (including the hot summer months) before sampling, the *S. bicolor* plants showed a high degree of AM fungal root colonization after eight weeks of cultivation. Charcoal application had a positive effect on AM fungal root colonization. To test the temperature tolerance of the sampled AM fungal strains, root and rhizosphere soil samples of the harvested *S. bicolor* plants were exposed to either – 4, 50, 70, or 100 °C for 48 hours. Control samples remained exposed to room temperature. The samples were then used to inoculate tomato plants grown in sterilized dune soil. Results revealed that AM fungal propagules retained high infectivity after exposure to -4 or 50 °C, while exposure to 70 °C lowered tomato root colonization compared to the control treatments. The plants grown in the presence of inoculum heated at 100 °C remained non-mycorrhizal. Previous soil amendment with charcoal had no impact on AM fungal temperature tolerance. Our findings suggest that AM fungi can well survive in agricultural soils of the UAE, even when these are left fallow during the hot summer months. Temperature tolerance of the sampled AM fungi exceeded that commonly found in other microorganisms and might be part of their adaptation to a hot desert environment.

Organic farming is indicated to preserve soil quality and its resilience against abiotic stresses. Among the threats to soil functionality exacerbated by climate change, salinization is one of the most harmful. Salinity governs the osmotic stress in plants and microbial cells, and the toxicity of specific ions can accelerate the decline of soil microbial pool. In this context, increased flooding risk caused by sea level rise can have detrimental effects on coastal soils. The intensity of the stress influences the ability of the system to recover, but proper soil management may reduce or delay the detrimental effects.

Two arable soils differing in management (conventional and organic) were selected and incubated in mesocosms for 5 and 25 days after exposure to 6-hour flooding with artificial seawater at increasing salt concentrations (0 - 34.5 g L<sup>-1</sup>). Analyses focused on biological aspects, i.e. soil microbial biomass C, soil ATP, respiration rates and soil enzymatic activities. Soil aliquots were air-dried after 5 days incubation and re-wetted, simulating the additional stress of drought, and analysed for soil water potential and ATP content.

Salinity negatively affected soil microbial biomass C while increasing soil respiration rates, which however declined at high salt concentrations. Salt stress seemed to affect the survival of some taxa rather than the overall microbial activity. In fact, despite ATP decreased with salinity, the ATP concentration of microbial biomass decreased significantly only at the highest salinity level. Enzymatic activities seemed poorly affected by the salt in the conventionally managed soil. Conversely, the organically managed soil showed increases in the alkaline phosphatase and cellulase activities and decreasing trends in leucine aminopeptidase with the increase of salinity. Nevertheless, this soil showed a better recovery from the drought stress compared to the conventional one.

Based on our results, we can expect a prompt response to salt stress in the case of organically managed soils, with reduced CO<sub>2</sub> emissions and preserved microbial biomass levels and enzymatic activities.

Soil monitoring is an important component for sustainable crop production. While soil chemical properties have generally been used for agricultural soil monitoring in Japan, soil biological properties are also considered to store much information reflecting soil condition.

Amplicon sequencing of 16S rRNA gene provides us with a snapshot of diverse soil bacterial communities in a high-throughput, cost-effective way. However, the application potential of 16S rRNA data for soil monitoring using machine learning has not yet been fully explored in comparison to chemical property data. In this study, we collected 375 agricultural soil samples from 278 sites across Japan, which covers wide range of soil types, weather conditions, and cultivated crops. We analyzed 16S rRNA data using supervised machine learning models to predict soil chemical properties and soil metadata including soil type and crop. Soil chemical properties, such as pH, carbon contents, and cations, could be predicted by XGBoost regression model using 16S rRNA data with the accuracy of normalized root means squared errors of less than 20%. Furthermore, 16S rRNA-based classification model predicted the soil metadata with higher accuracy than the model based on soil chemical properties. These results support that soil 16S rRNA sequencing provides useful information for monitoring agricultural soils.

Soil microorganisms orchestrate a myriad of important processes that influence planetary health. The mapping of Australia's soil microbiome presents a unique opportunity to gain deeper insights into the complex interplay between biotic and abiotic factors on a continental scale.

In this study, we investigate the determinants and controls of soil bacterial and fungal distribution across the Australia. Our dataset encompasses soil samples from diverse bioregions and soil types across the continent.

Our research reveals that at the continental level, the foremost driver of microbial distribution is the interplay between soil properties and climate factors. As expected, soils with similar characteristics tend to harbour similar bacterial and fungal communities, a finding reinforced by principal coordinate analysis.

Building on these insights, we developed digital soil mapping models that establish clear associations between observed microbial abundances and environmental variables. These models have enabled us to generate the first high-resolution continental maps of soil bacteria and fungi. These maps uncover intriguing microbial hotspots across Australia, such as the eastern coast, southeastern coast, and west coast, characterized by the dominance of Proteobacteria and Acidobacteria. For fungi, precipitation emerges as the dominant influence, with Ascomycota prevailing in the central region. Some of these microbial hotspots are situated in areas facing significant human pressure, rendering them vulnerable to environmental changes.

Focusing on a regional scale, our study focuses the effect of human activities on soil bacterial communities. The results underscore that land use changes have a more pronounced impact on the structure of rare sub-communities compared to their abundant counterparts. Abundant sub-communities tend to thrive in cropping environments, while rare sub-communities display lower prevalence and diversity in such areas. This suggests that cropping practices may lead to narrower niches, reduced adaptability to environmental changes, and biotic homogenisation.

Our research highlights the importance of considering soil heterogeneity when assessing the response of soil microbial communities to environmental changes.

Soil ecosystems provide habitats for diverse groups of organisms. Monitoring soil biodiversity over the long-term is necessary to identify proper soil management practices and to preserve soil ecosystem services. Archived soil series offer promising opportunities to characterize microbial temporal dynamics. However, soil microbes are usually studied using cryopreserved fresh soils, while almost all archived soils are dried and stored at room temperature.

The aims of the present project are to assess the feasibility of using dried soil samples for the study of microbial biodiversity, to estimate the potential biases compared to frozen samples, and then to use such soils to study the temporal trends of microbial communities in response to environmental changes.

Soil samples were obtained from two long term experiments located in Italy (CREA) and in Slovenia (ULBF). These soils were subjected to different management practices, and were collected in 2011 (or 2012), stored both as frozen and dried (oven-dried or air-dried). Thereafter, the same soils were collected in 2022 and again stored frozen and dried, though for a shorter period of time (7-8 months). DNA was extracted from all these samples and used to quantify the abundance of bacterial functional genes, for sequencing of bacterial V3-V4 16S rDNA to assess the bacterial composition and will also be used for enzymatic analyses.

For CREA samples, we observed no effect of storage conditions on bacterial communities, while the effects of tillage and sampling year were prominent. Conversely, for ULBF, different storage methods influenced the composition of the bacterial communities, while the effect of the different tillage practices resulted masked. It is possible that different physicochemical soil properties or the different soil drying procedure might determine a different preservation of bacterial DNA in dried soils.

Future perspectives include evaluating the effects of different drying procedures and studying the enzymatic activity of these soils to better understand the potential use of archived dried soil samples for soil biodiversity monitoring.

Restoration initiatives in drylands are often hampered by the harsh environmental conditions of these regions, which makes ecosystem restoration challenging. The use of direct seeding has emerged as a potentially effective strategy for large-scale rehabilitation of drylands, offering the prospect of substantial cost reductions. However, the refinement of this technique is imperative to increase seedling survival and establishment. In this context, biopriming arises as an upsurging technique to enhance seed germination and seedling establishment, with cyanobacteria among the most interesting beneficial microorganisms for biopriming applications.

This study evaluates the effect of seed biopriming with native biocrust-forming cyanobacteria on seed germination and radicle length in four plant species—two perennials (*Macrochloa tenacissima*, *Thymus hymenalis*) and two annuals (*Plantago ovata* and *Stipa capensis*)—chosen for their prevalence in the Mediterranean drylands. Experiment treatments consisted of seed biopriming with cyanobacteria inoculants (biomass + exudate), seed priming solely with cyanobacterial exudate, and control treatments which included seeds immersed in BG11 culture medium and distilled water. Four different native biocrust-forming cyanobacteria species (*Nostoc commune*, *Tolypothrix distorta*, *Trichocoleus desertorum*, and *Leptolyngbya frigida*) were employed for biopriming.

Results reveal that seed biopriming mostly exhibited neutral effects and above all, showed no inhibitory effect on seed germination. Nevertheless, significant positive effects on radicle length were observed in annual plants. Notably, *P. ovata* radicles were considerably larger when treated with cyanobacterial exudates, and *S. capensis* radicles were enhanced when primed with cyanobacterial biomass. These results underscore the species-specific nature of seed biopriming effects, emphasizing that proper selection of plant species, coupled with optimal biopriming treatment, can significantly improve plant survival and establishment in arid areas, thereby improving the overall success of restoration initiatives.

Soil microbial communities play an important role in shaping soil health, carbon (C), and nutrient cycling. However, land management practices such as afforestation, grazing, and grassland will influence soil bacterial and fungal communities and abundance is not clear. Furthermore, the impact of EU-subsidised agricultural best practices on soil microbiomes is not fully understood. Here, using DNA sequence and physical-chemical properties of soil samples collected in a countrywide soil survey in Hungary, we assessed the impact of different land management practices, and soil properties to develop an understanding of the drivers and patterns of soil bacteria and fungi in contrasting ecosystems. The results show that bacterial and fungal community composition and abundance significantly differed among land management practices, suggesting the sensitivity of soil microbiomes to soil disturbance. Furthermore, we found significant effects of physical and chemical soil properties on soil bacterial and fungi composition and abundance. Together, the results suggest that soil bacterial and fungal communities and abundance are driven by a much more complex interaction of land management practices and soil geochemical properties than generally considered. Consequently, land use/management history and soil geochemistry should be taken into account when developing mechanistic models for microbial dynamics and related soil health indicators.

The role of the soil microbiome in mediating important global change stresses to plants, including drought and extreme temperature, is becoming more widely known, but a critical question that largely remains unanswered is whether microbiome multifunctionality can be actively managed to promote a more sustainable future in agriculture? Vineyards represent a large potential source of ecological impact as they cover a vast portion of land worldwide, and also represent an important source of income for millions of people. In this study, we begin to identify the ways addition of microbial communities of whole vineyard soils to grapevines (i.e., microbiome management) can confer critical functions that increase plant tolerance to prolonged drought. We identified soil source-specific factors (e.g. mean annual precipitation) that selected microbial communities and functions that then differentially mitigated the negative effects of drought for one of two grapevine varieties in a large factorial growth experiment. This work highlights the potential of soil microbiome management to mitigate important climate stress factors that threaten sustainability in vineyards while promoting plant productivity.

Climate change is the main driver of biodiversity loss in terrestrial ecosystems. Soil microbial diversity losses will reduce multiple ecosystem functions, including soil carbon storage and nutrient cycling. Mediterranean forests are one of the hotspots of biodiversity in the world as well as one of the most threatened ecosystems by climate change. More intensive and longer drought periods are forecast for this region. However, how decreased precipitation will affect soil microbial diversity and if and how lithology will mediate the response remains poorly understood. Within the projects LITHOFOR and TRILOBITE, we aim to predict the response of forests to climate change. We selected a unique experimental set-up in the province of Málaga, South of Spain, where maritime pine forests grow on three different substrates in three Sierras along a precipitation gradient (spanning from 1300 to 600 mm annual precipitation). Soil samples from 45 forest plots were collected in the three locations where pine forests grow on three different lithologies (calcareous, metapelite and peridotite). Soil microbial community biodiversity was assessed using high throughput sequencing of 16S rRNA genes (bacteria), the ITS region (fungi) and 18S rRNA genes (eukaryotes). Both precipitation and lithology significantly influenced microbial community structure, showing increased diversity in sites laying on peridotite soils and with the lowest precipitation. While soil microbial diversity was similar among lithologies at the wettest site, diversity increased with increasing aridity, particularly in the most adverse substrate, peridotite. Remarkably, the percentage of shared taxa between the different lithologies increased with aridity. The main variables driving microbial community structure were soil physicochemical characteristics such as Mg/Ca, texture, Ni, pH and CaCO<sub>3</sub> and forest structure (growth, diameter and age). Our results highlight the importance of bedrock and lithological substrates for the response of soil microbiome to climate change. Our study suggests that stressful edaphoclimatic conditions, imposed by aridity and lithology, induce higher bacterial, fungal, and non-fungal eukaryotes diversity supporting the stress gradient hypothesis.

The use of indicators allows the study of soil health by reducing the necessary number of analytical determinations without putting the decision-making capacity at risk. The different biological parameters that can be analyzed in the soil have demonstrated their usefulness as indicators in different cases: contamination, physical degradation, differences between management in agricultural soils, etc. The analysis of enzymatic activities is shown to be one of the most used biological indicators in the study of soil health. However, there is no consensus on how to analyze the results: some authors use the data on enzymatic activities directly and others normalize them with respect to the organic carbon (TOC) or with the geometric mean of the activities (GMEAN). The objective of this work was to evaluate the influence of different methods of enzymatic activities normalization in olive grove soils with different cover crops. The study area was located in an experimental olive grove, in the center of Iberian Peninsula (Finca Experimental La Chimenea, IMIDRA, Spain). The soil was managed with four treatments: i) conventional tillage, ii) permanent cover of *Brachypodium distachyon* (L.) P. Beauv., iii) permanent cover of spontaneous vegetation and iv) annual cover crop of bitter vetch (*Vicia ervilia* (L.) Willd). Enzymatic activities related to the C, N, P and S cycles were analyzed: beta-glucosidase, urease, phosphatase and arylsulfatase, respectively. The results obtained by performing Principal Component Analysis (PCA) were compared to the unnormalized enzyme activities (AE), normalized by TOC (AE/TOC) and normalized by GMEAN (AE/GMEAN). The PCA performed with AE and AE/GMEAN obtained similar variance explanation percentages, with the worst results for AE/TOC. The distribution of the enzymatic activities in the PCA of AE would be due to the relationship they present with the TOC, reducing the capacity for analysis of the enzymatic activities, while the ordination in the AE/GMEAN facilitates a better interpretation of the relationships between activities by reducing the influence of covariates.

Soil microbes mediate biogeochemical cycling of essential nutrients (N, P, K, S) and assist in organic matter (OM) decomposition, preserving soil fertility and supporting plant productivity. Despite evidence, more research is needed on the soil-plant-microorganism (SPM) system with organic amendments. With the increasing interest in alternative plant nutrition methods, addressing this topic is justified. A potential alternative could be hydrochar (HC), a carbonaceous material obtained through the treatment of biomass via a hydrothermal carbonization process.

This study employs a multidisciplinary approach to examine the effects of chicken manure HC on the SPM system, evaluating soil microorganism abundance and activity, OM quality and quantity, nutrient availability, and sunflower plant performance under different irrigation conditions. HC was applied to a Cambisol at rates of 3.25 and 6.5 t ha<sup>-1</sup> (HC-3.25, HC-6.5), with mineral fertilizer treatments providing equivalent total N contributions for comparison. Sunflower plants were grown in pots under two irrigation conditions (60% and 30% of the soil water holding capacity). Plants were harvested after 77 days, and macronutrient content in soil and plants was analyzed. The quality of OM was assessed using <sup>13</sup>C NMR. Microorganism analyses included counting colony-forming units and using qPCR to measure 16S rRNA and ITS gene copies for bacteria and fungi, plus bacterial acid phosphatase (PHO), urease, and B-glucosidase (BG) gene copies. Microbial activity was evaluated by analyzing soil respiration and dehydrogenase, PHO, and BG activities.

Results revealed that HC-6.5 treated soils had higher bacteria and fungi abundance and increased microbial activity. Particularly under well-irrigated conditions, these soils also exhibited a higher proportion of available K and S for plants, leading to improved nutrient uptake efficiency. Since the concentration of both elements did not rise after HC application at the beginning of the experiment, the availability changes are presumed to result from microorganism-mediated processes stimulated by HC. Our findings emphasize that HC amendment impact on soil involves interactions among climate, application rate, plant physiology, and microbial activity.

Due to challenging climatic conditions, the rising lack of fertilizer resources and the increasing demand for sustainable agriculture, the role of healthy soils is expected to become more important in the future. Soil health is a key deliverable of the European biodiversity strategy for 2030 contributing to the objectives of the EU Green Deal. Healthy soils have the capacity to lower the impact of climatic stress, reduce the extend of soil-born plant diseases and pests as well as directly to support plant growth via efficient natural nutrient cycles, an improved physical soil structure as well as optimized plant nutrient uptake. Those benefits have been linked to well-developed soil food webs, the presence of natural antagonists of pest and diseases, as well as plant growth promoting microbes. The management of plant-parasitic nematodes, that currently mainly relies on the use of synthetic nematicides could highly benefit from these organisms. Consequently, we need to better understand how soil applied nematicides interact with organisms that contribute to the overall soil health network and to include both into an integrated nematode management approach. Within our talk, we will share recent data on the compatibility of Fluazaindolizine (Salibro™), a novel nematicide developed by Corteva Agriscience, with various beneficial organism including free-living nematodes, nematode & disease suppressive soil fungi as well as beneficial soil bacteria.

Biopores are of crucial importance in the organization of soil structure, water infiltration and air circulation between the surface and the deep soil. Despite their importance in soil functioning, there is a lack of comprehensive knowledge regarding the contribution of soil engineers to the formation of these biopores and their regeneration rates in field conditions.

To this end, we aimed to investigate: (1) the relationships between soil engineers, i.e., earthworms, ants, termites, beetles and millipedes, and biopores and (2) the potential use of organic matter residues to stimulate macrofauna activity and faster the generation of soil biopores. Our experimental approach involved repacking soil cores into soil bags to create bioporosity-free cores, where soil engineers could colonize them. Soil bags were incubated in twelve contrasted pedoclimatic study sites including five countries (France, Vietnam, India, Laos and Thailand) for a year. After 12 months, the volume of biopores imaged and measured by X-ray computed tomography in soil bags was compared to the volume of biopores measured in control cores from each of the study sites. Furthermore, we explored the relationships between the volume and shape of biopores generated in soil bags with the communities of soil engineers and soil pedoclimatic conditions.

We showed, in most of cases, a complete regeneration of the volume of biopores after 12 months regardless the addition of organic residues or the pedoclimate conditions. The sites with a greater earthworm population exhibited the greatest rates of regeneration. The co-inertia analysis, allowing to compare the diameter and complexity of the regenerated biopores to the soil engineers was not statistically significant. This suggest that either this approach or the 3D parameters used were not suitable for identifying the origin of biopores.

In conclusion, our findings demonstrated that biopores are rapidly regenerated, mainly by earthworm activities regardless the pedoclimatic conditions. However, understanding the specific contribution of soil engineers to biopores remain a complex puzzle to unravel.

**Keywords:** Soil bags, Biopores regeneration, Soil engineers, Macrofauna

#### REMEDIATION OF HEAVY METAL CONTAMINATED SOIL IMPACTED PLANT RESIDUE UPTAKE INTO MICROBIAL AND MICROARTHROPODAL GROUPS AS REVEALED BY <sup>13</sup>C FATTY ACIDS ANALYSIS

A. WATZINGER, C. NOLLER, J. WISSUWA, R. HOOD-NOWOTNY, W. FRIESL-HANL

BOKU University of Natural Resources and Life Sciences, Tulln, AUSTRIA

Heavy metal contamination of soils has a great impact on soil biota and carbon turnover. Soil washing with a chelating agent is a potential remediation technique to remove heavy metals. The recovery of the soil biota following washing and associated impact on the soil carbon cycle were investigated in a pot trial using the heavy metal contaminated soil and two washed variants, one amended with vermicompost and biochar. Carbon stable isotope (<sup>13</sup>C) labeled maize straw was applied as a carbon source. Stable isotopes were measured in the fatty acids (FA) of single microarthropodal groups (Collembola, Gamasina, Oribatida, Astigmata) and the microbial phospholipid fatty acids (PLFA).

Total microbial biomass and <sup>13</sup>C incorporation into microorganisms was significantly increased and the PLFA pattern shifted after remediation of heavy metal contaminated soil. In accordance, the abundance of the microarthropodal groups Gamasina, Oribatida and Collembola were also increased. The relative FA patterns of those groups differentiated significantly among each other, but were not influenced by soil treatment, meaning that the altered microbial PLFA pattern was not transferred into microarthropodal FA. However, the amount of FA per individual was significantly affected by both soil treatment and groups of microarthropods, with higher FA per individual in the contaminated soil than washed ones. Incorporation of <sup>13</sup>C plant residues in total microarthropods were significantly higher in washed soils, where Gamasina, Astigmata and Collembola incorporated more plant residues in washed soils, while <sup>13</sup>C incorporation of Oribatida was constant over the different soil treatments.

These first results revealed, that the relative FA pattern of the microarthropodal groups was not affected by changes in the microbial PLFA pattern due to soil treatments. Differences in the absolute FA amount per individual and the <sup>13</sup>C uptake were rather governed by the life and reproduction strategies, with higher fattiness and low abundance under adverse environmental conditions, constant <sup>13</sup>C incorporation in K-strategist and higher <sup>13</sup>C incorporation of mainly r-strategist under improved conditions.

<sup>3</sup> Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, Private Bag x20 Hatfield, South Af, Pretoria, SOUTH AFRICA

Intensification of staple crops through conventional agricultural practices with synthetic inputs has yielded positive outcomes in food security but with negative environmental impacts. Ecological intensification intercropping such as maize edible-legume intercropping (MLI) systems has the potential to enhance soil health and agrobiodiversity and significantly influences crop productivity. However, mechanism underlying enhancement of biological health of soils has not been understood in detail. This study investigated the shifts in rhizosphere and maize-root microbiomes and associated soil physico-chemical parameters in MLI systems of smallholder farms compared to maize-monoculture cropping (MMC) systems. Maize-root and soil samples were collected from twenty-five farms each conditioned by MLI and MMC systems in eastern Kenya. Soil characteristics were assessed using Black oxidation and Walkley methods. High-throughput amplicon sequencing was employed to analyze fungal and bacterial communities, predicting their functional roles and diversity. The different MLI systems significantly impacted soil and maize-root microbial communities, resulting in distinct microbe sets. Specific fungal and bacterial genera and species were mainly influenced and enriched in the MLI systems (e.g., *Bionectria solani*, *Sarocladium zeae*, *Fusarium algeriense*, and *Acremonium persicinum* for fungi, and *Bradyrhizobium elkanii*, *Enterobacter roggenkampii*, *Pantoea dispersa* and *Mitsuaria chitosanitabida* for bacteria), which contribute to nutrient solubilization, decomposition, carbon utilization, plant protection, bio-insecticides/fertilizer production, and nitrogen fixation. Conversely, the MMC systems enriched phytopathogenic microbial species like *Sphingomonas leidyi* and *Alternaria argroxiphii*. Each MLI system exhibited a unique composition of fungal and bacterial communities that shape belowground biodiversity, notably affecting soil attributes, plant well-being, disease control, and agroecological services. Indeed, soil physico-chemical properties including pH, nitrogen, organic carbon, phosphorus, and potassium were enriched in MLI compared to MMC cropping systems. Thus, diversification of agroecosystems with MLI systems enhances soil properties and shifts rhizosphere and maize-root microbiome in favor of ecologically important microbial communities.

#### GORSE POSITIVE-EFFECTS ON SOIL RESILIENCE AND CROP PERFORMANCES

D BOLDRIN<sup>1</sup>, E PASCON<sup>2</sup>, P. ..I. IANNETTA<sup>1</sup>, E JAMES<sup>1</sup>, C KRYNAUW<sup>1</sup>, K LOADES<sup>1</sup>

<sup>2</sup> Université Clermont Auvergne, Clermont-Ferrand, FRANCE

The agricultural ecosystem faces the constant risk of soil degradation and unsustainable use of synthetic nitrogen fertilisers. A paradigm shift, from outsourcing and high inputs to 'ecological intensification' is required. Transformation towards such an approach requires changing the perception that all non-crop species within the farmed environment are 'weeds' that require removal. In fact, their rapid establishment and synanthropic adaptation make these 'weeds' unexplored resources, and good candidates to provide ecosystem services in disturbed and degrading environments. An excellent example of this would be 'gorse' (*Ulex europaeus* L.), a woody legume native to Britain.

Therefore, we decided to evaluate the potential ecosystem services provided by gorse for soil resilience and crop performance, with soil samples collected at different distances from established gorse bushes (from beneath the gorse to an adjacent cultivated field).

In the laboratory, soil samples were sieved and tested for aggregate stability and recovery after compaction stress. Sampled soils were also used to cultivate barley and spinach in a glasshouse, and hence assess the effects of gorse (mediated by soil) upon crop-performances. Soil aggregates collected from the centre of gorse showed the greatest stability. In contrast, soil collected from the cultivated field was the most unstable. Soil resilience to compaction stress highlighted similar results. After the application of 200 kPa compaction-stress, equivalent to the stress exerted by a tractor tyre, soil collected from beneath gorse bushes showed greater elasticity and recovery. In contrast, field soil showed poor resilience to compaction stress. Barley and spinach plants growing in soil collected close to the gorse also had greater chlorophyll content, indicative of improved nutrient (N) availability.

In conclusion, gorse can have positive effects on both soil- and crop-health, and its utility for agroforestry needs greater consideration and further research.

##### BARLEY-PEA INTERCROPPING ALTERS SOIL MICROBIAL FUNCTIONAL TRAITS BUT NOT CARBON USE EFFICIENCY

<sup>5</sup> The James Hutton Institute, Aberdeen, UNITED KINGDOM

##### Background and objective

Intercropping can mitigate the adverse environmental impacts of conventional agriculture. Intercropping alters soil microbial communities but its effects on soil microbial functions driving key soil processes are unclear. This study examined microbial functional traits associated with carbon and nutrient cycling – including carbon use efficiency (CUE), extracellular enzyme activities (EEA), and microbial catabolic diversity – in barley-pea intercropping in soils with contrasting management legacies.

##### Methods

Barley-pea, barley-barley and pea-pea combinations were grown for 50 days in soils with a history of conventional and sustainable management under laboratory conditions. Microbial CUE, EEAs and microbial catabolic diversity were estimated using <sup>13</sup>C isotope tracing, fluorometric assays and MicroResp™, respectively.

##### Results

Intercropping did not affect microbial CUE but did increase microbial catabolic diversity and generally decrease EEAs. Compared to the average of the monocrops, barley-pea intercropping decreased the potential activities of cellobiohydrolase, b-1,-4-Nacetylglucosaminidase and acid phosphatase but increased those of b-glucosidase in the conventional soil and leucine aminopeptidase in the sustainable soil. Intercropping also altered microbial substrate utilisation profiles and increased microbial catabolic diversity. Soil management legacy had stronger effects on these microbial traits than crop combination. Regardless of crop combination, sustainable management enhanced CUE, EEAs and catabolic diversity relative to conventional management practice.

##### Conclusion

Barley-pea intercropping modifies the ability of soil microbial communities to decompose organic substrates while maintaining their efficiency to utilise these substrates for their growth and metabolic activities. This implies that intercropping and sustainable management practice alter the balance between the release and retention of carbon and nutrient in soils, potentially favouring retention.

Agroforestry makes herbaceous and tree cultivation more sustainable and resilient (Terasaki Hart et al. 2023). Reduced tillage improves soil health and reduces the environmental impact of agriculture (Betancur-Corredor et al. 2022). However, few studies analyzed the short-term effects of switching from monoculture to agroforestry, and from ploughing to reduced tillage, on soil properties (soil organic carbon [SOC]; permanganate oxidable carbon [POX-C], available phosphorus [Olsen P], and bulk density [BD]) during the first years of conversion. The trial was performed in a sub-alkaline (pH 8.2) clay loam soil at Cesa Living Lab (Arezzo province, Italy) during two growing seasons (GS). The experimental design was a randomized complete block design with three blocks and three replicates by block. The main factor was the tillage intensity (plough tillage vs reduced tillage), while the subplot was the presence of alley cropping (none, olive (*Olea europaea* L.), and hazelnut (*Corylus avellana* L.) trees) against an herbaceous monoculture. Three different soil depths were investigated (0-5 cm, 5-10 cm, and 10-20 cm). No significant differences were reported in SOC between reduced and conventional tillage in the topsoil layers. On the contrary, a significantly lower SOC was reported in reduced compared to conventional tillage at the deeper soil layer (10-20 cm). Similar results were obtained for POX-C, as significant differences were observed in reduced compared to plough tillage at 10-20 cm soil depth but not in the top layers. As regards BD, a significant increase was detected in reduced tillage compared to the plough tillage. However, alley cropping did not significantly affect soil BD compared to monoculture. Olsen P was significantly higher in plough tillage than in reduced tillage in the 10-20 cm soil layer, while no significant differences were observed in the topsoil. In addition, a significant shift in microbiological population was observed for the tillage and cropping system. No significant differences were reported for grain yield between the cropping systems and between the two tillage intensities.

NITROGEN CYCLING IN A DIVERSIFIED ROW-CROP SYSTEM: ROTATIONAL RESPONSES, 15N TRACING AND SOIL HEALTH INDICATORS.

J. BARRA NETTO-FERREIRA, G. MALTAIS-LANDRY, C.H. WILSON

University of Florida, Gainesville, USA

The substitution of fallow periods with a crop (cash crop or cover crop) generates crop residues that contribute to soil organic matter and soil biological activity, which could affect soil fertility and nitrogen (N) cycling. Cover crops (CCs) are often adopted in diversified agroecosystems, yet their adoption is constrained by limited profitability. A dual-purpose crop could fit as an alternative, providing the soil benefits of a cover crop while supplying farmers with income through harvest. We conducted this study in Northern Florida (United States) to investigate how chickpea (a novel cash crop in the area) affects nitrogen cycling in a corn rotation system compared to systems with CCs or a bare fallow. Four treatments were applied during winter and consisted of 1) a control (maintained weed-free with herbicides), 2) cereal rye CC, 3) crimson clover CC, and 4) a commercial variety of chickpea. After terminating winter crops (WCs), 15N-labeled WC-residues were incorporated into subplots, followed by corn planting fertilized with two N rates. Plant biomass was collected at the termination of the crops and soil was sampled after residue incorporation (WCs and corn) to assess soil health indicators, corn responses, and 15N recovery. After WCs termination, chickpea had statistically higher mineralization of carbon and N in contrast to fallow (Figure 1), with clover and rye being intermediate. In contrast, there were no statistically significant differences among WCs at corn harvest. Similarly, WCs did not increase corn yields, grain N concentrations, and whole-plant N accumulation in comparison to fallow (Figure 2). Notably, chickpea resulted in a lower relative yield than fallow at the higher N rate (Figure 2). Finally, as the recovery of 15N from WC-derived residues in corn (biomass and grain) was limited (3 to 11%), this suggests that other WC benefits, such as nutrient retention, improvements in soil health and/or microbial activity, may play a more pivotal role to the system's overall sustainability.

Cover crops introduction in olive orchards, as an alternative for conventional tillage, involving changes in the soil's physical-chemical and biological properties. These cover crops act as a protective barrier against erosion, thereby enhancing other ecosystem services such as carbon sequestration through an increase in organic matter content, or by increasing soil biodiversity through nutrients recirculation to the soil, allowing greater bioavailability for microorganisms. Cover crop roots release sugar and amino acids, which can directly influence soil microorganism populations and biomass. Therefore, the use of different plant species in cover crops can also affect the composition of soil microorganism populations and their involvement in biogeochemical cycles. The aim of this work is to evaluate how soil management, with different types of cover crops, influences soil microbiota and their role in nitrogen cycling. A trial was performed in an intensive olive orchard of 238 trees·ha<sup>-1</sup> on the Experimental Farm "La Chimenea" (IMIDRA), southern Madrid. There were four different soil managements: i) conventional tillage, ii) permanent grass cover (*Brachypodium distachyon* (L.) P. Beauv.), iii) permanent spontaneous vegetation and iv) annual legume cover (*Vicia ervilia* (L.) Willd). Soil sampling was carried out at four depths (0-5cm, 5-10cm, 10-20cm and 20-30cm) for the analysis of specific physical-chemical and microbiological properties. Microbiological analysis consisted on extracting DNA from the soil samples and quantifying it by qPCR, determining the abundance of fungi (ITS), bacteria, and total archaea (16SrRNA), along with the *amoA*, *amoB*, and *ureC* genes. Preliminary results indicate that the main differences in the abundance of bacterial population happens in the depth factor, being greater at 0-5cm depth than beneath ( $p < 0.05$ ). Regarding soil management, fungal population increases under legume cover comparing to other cover crops ( $p < 0.05$ ). Likewise, the abundance of *ureC* is higher at 0-5cm depth ( $p < 0.05$ ). Therefore, the use of different types of cover crops as soil management measures influences the composition of soil microbiota and nutrient cycling and thus, the ecosystem services they provide.

Agricultural production of Mediterranean regions is forecasted to be threatened by drought. To improve the sustainability and resilience of agricultural systems it has been suggested to augment plant biodiversity to better face various stresses. In this study, we focused on intra-specific diversity, which may be increased by evolutionary Populations (EP) based on evolved plant variety mixtures and presenting a higher degree of genetic diversity than conventional wheat. EP usually show lower input needs and higher buffering capacity in response to various stresses. We hypothesised that introduction of EP in Mediterranean regions impacts soil functioning through their effect on soil organic matter (SOM) and that EP-soil relationship is stronger in similar sites than those they were let to evolve during their creation.

We conducted a field experiment in Italy (Parma and Roma). We compare a conventional wheat to two wheat EPs, in rotations with legumes. Rhizosphere soil was sampled after the EP cultivation and analysed SOM characteristics using C, N contents and SOM signatures by mid-infrared spectroscopy as well as soil microbial parameters by community characterisation using EL-FAME analysis and enzyme activities.

EP, regardless of their cultivation areas, showed no effect on the measured parameters compared to conventional wheat. Nevertheless, the result showed that the organisation of the microbial community was affected in Parma by EP that evolved in Parma-like conditions with a significantly higher Gram-:Gram+ ratio. We also observed that enzymes activities were significantly higher in both sites under EP that evolved in similar conditions. In Parma, rotation with pea induced a decrease of -49 % of the aliphatic:aromatic ratio compounds in soil. In Roma, a significant decrease of N content (-17 %) under cicer rotation was observed. That decrease was reduced significantly when EP were cultivated after cicer compared to the conventional wheat. Finally, we observed that SOM signature in soil was more related to soil enzyme activities (co-inertia RV: 0.70) than to microbial community (RV: 0.33).

#### INTERCROPPING IMPROVES SOIL HEALTH VIA SUPPRESSING SOIL-BORNE PATHOGEN

X.YIN<sup>1</sup>, R - YU<sup>1</sup>, C - WANG<sup>2</sup>, S - YANG<sup>2</sup>, L LI<sup>1</sup>

<sup>1</sup> China Agricultural University, Beijing, CHINA

<sup>2</sup> Gansu Academy of Agricultural Sciences, Lanzhou, CHINA

Soil is one of the richest life ecosystems on the earth. Soil-borne diseases by fungal or bacterial pathogens cause severe damage in agricultural production. Intercropping, growing at least two crops on the same field at the same time, is one of the main practices to control crop diseases. The aim of this study is to determine soil health and fusarium wilt disease in faba beans/maize intercropping.

Based on a long-term field experiment initiated in 2009, which included three P application rates (0, 40 and 80 kg P ha<sup>-1</sup>) and faba bean/maize intercropping and corresponding monocultures, in 2020-2023, physical, chemical and biological properties of soils were measured, and soil health index (SHI) was calculated using linear scoring function methods, and a minimum data set based on PCA method. Real-time quantitative PCR was conducted to measure the gene copies of *Fusarium oxysporum* and *Fusarium solani* in rhizosphere soils and root endosphere of faba bean.

Results showed that the total grain yield of maize/faba bean intercropping was 31.8% (30.5% -33.7%) greater than the weighted means of monocultures. Simultaneously, intercropping enhanced SHI by 10.2%, where average SHIs were 0.76 and 0.69 for intercropping systems and the weighted means of corresponding monocultures across three P levels. Intercropping reduced the fusarium wilt disease incidence of faba bean by 8.1%-30.3%, and the gene copies of *F. oxysporum* by 18.7-37.7% and *F. solani* by 15.4-18.4% in root endosphere, compared to monocultured faba bean. Furthermore, intercropping decreased the gene copies of *F. oxysporum* by 4.9%-29.9% and *F. solani* by 4.5%-38.9% in rhizosphere soils of faba bean. Intercropping increased bacterial richness by 17.5% and Shannon index by 10.6% relative to monoculture.

Our findings indicated that intercropping improves soil health via suppressing soil pathogen.

#### LONG-TERM INTERCROPPING ENHANCES SOIL ORGANIC CARBON THROUGH MULTIPLE FACETS

R. YU <sup>1</sup>, Y. XING <sup>1</sup>, J. ZHANG <sup>2</sup>, X. BAO <sup>2</sup>, L. LI <sup>1</sup>

<sup>1</sup> China Agricultural University, Beijing, CHINA

<sup>2</sup> Gansu Academy of Agricultural Sciences, Lanzhou, CHINA

Increasing plant diversity of agroecosystems, such as intercropping, may enhance soil organic carbon (SOC), especially in the long term. However, multiple facets affect soil C degradation and fixation; whether and how long-term intercropping affects SOC is largely underestimated. Based on a long-term field experiment since 2009 in Wuwei City, Gansu Province, PR China, we investigated the effects of cropping systems (maize monoculture, faba bean monoculture, chickpea monoculture, soybean monoculture, oilseed rape monoculture, faba bean/maize, chickpea/maize, soybean/maize and oilseed rape/maize intercropping) on productivity and SOC.

Long-term intercropping enhanced grain yield by 26-42% compared with the weighted mean of monocultures, which also increased root C inputs. Intercropping increased SOC by 6-10% compared with monoculture. We explore the potential effects of C protection and fixation in this experiment. The results showed that intercropping promoted the formation of >2 mm macroaggregate, and enhanced microbial functional genes related to C fixation while decreasing those related to C degradation (GeoChip), improving the physical protection of soil C. We also found that intercropping improved the C-related enzyme activity, which may facilitate microbial C acquisition. Improved relative abundance of copiotrophic species (*r*-strategy) in intercropping, such as Cytophagales, Rhizobiales, and Gammaproteobacteria, partly promoted the accumulation of SOC. The more complex microbial network and enhanced microbial- and plant-derived necromass C also contribute to the accumulation of SOC in intercropping systems than monocultures.

In conclusion, intercropping increased productivity and SOC, which results from the improvement of soil physical structure (physical protection) and the microbial mechanisms (e.g., the relative abundance of *r*-strategy microbiome and increased necromass C). This study provides a theoretical basis for improving the sustainable development of agroecosystems by intercropping.

#### CROP ROTATION: IMPACTS ON PHOSPHORUS COMPOSITION IN SOIL AGGREGATES AND MICROBIAL COMMUNITY STRUCTURE

V. COZZOLINO, M VERRILLO, S CANGEMI, V DI MEO, R S DEL GAUDIO, V VALENTINO, R SPACCINI, F DE FILIPPIS

Department of Agricultural Sciences, Università di Napoli Federico II, Portici, ITALY

Understanding the influence of long-term crop management practices on soil phosphorus composition in aggregates and the soil microbial community is critical for linking soil microbial flora with ecosystem processes such as those involved in soil phosphorus cycling. We collected soil samples from a long-term experimental field (over 25 years) at the 0 to 20 cm depth. We investigated the effects of two crop rotation, 1. maize/maize (MM), 2. maize/fava bean (MF) compared to a control plot, undisturbed soil, (CT), on the distribution of soil P composition determined by  $^{31}\text{P}$  nuclear magnetic resonance (NMR), total P, inorganic and organic, and available P in different size fractions of soil aggregates (1–2, 0.5–1, 0.25–0.5, and <0.25 mm). To investigate the effects on bacterial and fungal community structure we used 16S rRNA gene and Internal Transcribed Spacer (ITS) high-throughput sequencing. The results showed that the different treatments influenced the concentrations of soil phosphate monoesters and diesters, and soil aggregate stability significantly. The MF rotation, compared to MM, increased the structural stability and the state of aggregation of the soil. Furthermore, this type of rotation increased the concentration of total organic P and, in particular, of specific forms of organic P, monoesters and diesters. The CT treatment had the highest available P and organic P proportion in total P but not more total soil P content. Furthermore, the small sized macroaggregates (1–0.5mm) showed the largest concentrations of monoesters and diesters, although in undisturbed soil the two classes of molecules are present in lower concentrations in the fractions of aggregates having the smallest dimensions (<0.25mm). The soil microbiota and mycobiota composition were significantly impacted by the different treatments. Our results suggest that long-term management practices influence the structural potential of soil microbial community and soil P turnover that varies between different sized soil aggregates. These findings provide a strong framework to determine the impact of management practices on soil P and soil health.

African countries have continued to address the myriad of challenges faced in the agriculture to solve its nutrition and food security challenges. We examined the relationship between agronomic management practices and crop nutritional composition of five major food crops in Nigeria and Ghana. The crops include cassava (*Manihot esculenta* Cranz), corn (*Zea Mays*), cowpea (*Vigna unguiculata*), rice (*Oryza sativa*) and green amaranth (*Amaranthus viridis*). The study involved 2 fields per state \* 5 crops \* 3 ecoregions\* 2 crop varieties in Nigeria and 2 fields per region \* 5 crops \* 2 ecoregions \* 2 crop varieties in Ghana. Plant samples were collected randomly on farmers' fields and processed for chemical nutritional analysis including ash, fat, fiber, protein, total carbohydrate, food energy value, mineral content, and tannin using methods approved by the Association of Official Analytical Chemists. Questionnaires were administered to crop producers to obtain relevant information on agronomic practices. In Nigeria and Ghana 58 and 85 % respectively reported full tillage, 15 and 13 % respectively have adopted the no-till practice, and 28 and 2 % respectively used reduced tillage. About 50 % of the farmers in both countries reported no fertilizer use while 25 -38 % used synthetic fertilizers and less than 6 - 16 % farmers used organic fertilizers. Nutrient composition varied by crop by country. Conservation farming practices such as reduced/no-tillage and the application of chemical and/or organic fertilizers were main factors driving nutrient density of these crops in both countries. Ecoregion and soil management practices played a significant role in influencing nutrient composition/density. A more nutrient-dense values were seen for crops evaluated compared to that reported by FAO. Data obtained was used to create an open and accessible nutrient database ([www.afrinutridata.com](http://www.afrinutridata.com)) to improve information accessibility of crop nutrition and improvements in Africa. In conclusion, soil health management practices and fertilizer use have the potential to improve the nutrient densities of crops across various ecoregions.

The western flank of the Andes in Central Chile holds unique significance, encompassing a thin strip of land with one of the world's few Mediterranean climates on its high summits. While the soils of the Central Depression and Coastal Range have been extensively studied, the soils of the Andes remain largely unknown. This study examines eleven soil profiles distributed across the lower Andean belt (2500- <3500 masl), the upper Andean belt (3500- <3700 masl), and the nival/desert belt (>3700 masl). Results reveal remarkable variability in soil properties and types over short distances. Along the altitudinal gradient, different drivers influence pedogenic processes. In the lower Andean belt, organisms and weathering play a primary role in forming Mollic, Cambic, and Histic horizons. The upper belt exhibits intensive illuviation, evident in the prevalence of argillic horizons. Above the plant zone, cryogenic processes dominate, leading to features like ice wedges, sorted polygons, lenticular and granular structures in depth, as well as aeolian processes resulting in desert pavement and vesicular horizons. This unique assemblage of features in the upper Andean belts resembles those found in polar desert areas of the northern and southern hemispheres, unreported outside these specific regions. The distinct characteristics of the soils and associated processes in this Andean region prompt questions about the conditions giving rise to them. This work highlights the presence of soils in areas presumed to be primarily covered by rocks, offering valuable insights into soil properties and processes in a region previously unexplored by soil science.

#### POST-FIRE PHOSPHORUS ENRICHMENT PROMOTES NITROGEN RETENTION BY ATTENUATING SOIL NET NITROGEN MINERALIZATION IN BOREAL FORESTS

J. XU, H. SHEN, Z. DAI

Zhejiang University, College of Environmental and Resource Sciences, Hangzhou, CHINA

Net nitrogen mineralization ( $N_{min}$ ) is a critical process regulating soil nitrogen (N) availability and the direction and rate of post-fire vegetation succession in N-limited boreal forests. How microorganisms respond to the post-fire N:P (phosphorus) imbalance to alter soil  $N_{min}$  remains unclear, especially for boreal forest ecosystems. Here, we investigated post-fire N-P dynamics using a global-scale meta-analysis of 377 observations combined with an intensive regional-scale sampling of 17 boreal forests in the Greater Khingan Mountains (Inner Mongolia-China). We found that post-fire boreal forests had an increased risk of N loss by accelerated  $N_{min}$  compared to tropical forests. The post-fire N:P imbalance created by P enrichment acts as an “N retention” strategy by inhibiting  $N_{min}$  in N-limited boreal forests. This strategy is attributed to enhanced microbial N-use efficiency and N immobilization. These findings demonstrate that post-fire N-P interactions play an essential role in maintaining ecological balance and functions in boreal forests.

#### ALPINE WETLAND DEGRADATION IN THE NORTHERN MALOTI-DRAKENSBERG OF SOUTHERN AFRICA: ON THE NEED FOR BASELINE RESEARCH

J. VAN TOL<sup>1</sup>, J. DELVES<sup>2</sup>, J.J. KOTZE<sup>1</sup>, P. CHATANGA<sup>3</sup>, V.R. CLARK<sup>1</sup>

<sup>1</sup> University of the Free State, Bloemfontein, SOUTH AFRICA

<sup>2</sup> Eurac Research, Bolzano, ITALY

<sup>3</sup> National University of Lesotho, Roma, LESOTHO

The montane and alpine wetland soils of the Maloti-Drakensberg region hold immense significance as unique systems on the African continent. They play a crucial role in water regulation and provision in southern Africa, carbon sequestration and hosting unique organisms. Despite their vital role, these wetlands are rapidly deteriorating and face a critical endangerment status. However, our understanding of the causes and extent of their degradation remains limited, emphasizing the need for comprehensive baseline research. The objective of this paper is to contribute to the understanding of wetland degradation in the northern Maloti-Drakensberg and propose specific research priorities within an existing framework to address knowledge gaps. Additionally, it aims to raise awareness about the crucial importance of preserving these alpine wetlands in the face of environmental changes.

Utilizing keywords related to Alpine Wetlands in Lesotho, we conducted searches across databases and employed citation snowballing for additional publications. Our interpretations were validated through site visits and aerial/satellite imagery analysis.

While it has conventionally been believed that wetland degradation is primarily driven by livestock overgrazing within the tragedy of the commons narrative, the lack of baseline data to support this notion is alarming. It is essential to explore other potential drivers and assess their prominence, such as road infrastructure and the impact of ice rats. Several key research priorities, including measuring baseline ecological attributes, conducting socio-economic assessments of resource utilization, and monitoring temporal changes and landscape dynamics were identified in this paper. This baseline research will be the primary focus of the recently established Long-Term Socio-Ecological Research (LTSER) platform in the northern Maloti-Drakensberg, known as the Mount-Aux-Sources LTSER.

By addressing the existing knowledge gaps and advocating for the preservation of these alpine wetlands, this paper aims to contribute to the broader understanding of wetland degradation and promote sustainable management practices in the northern Maloti-Drakensberg region.

#### PRESCRIBED BURNING TREATMENTS DO NOT IMPACT THE MINERAL SOIL HORIZON IN THE SOUTHERN EUROPEAN ALPS

S. NEGRI<sup>1</sup>, L. CANALE<sup>1</sup>, A. BONO<sup>1</sup>, S. VOYRON<sup>2,3</sup>, F. SECCHI<sup>1</sup>, D. ASCOLI<sup>1</sup>, E. BONIFACIO<sup>1</sup>

Wildfires are ecosystem processes in the majority of terrestrial biomes; nowadays, global change is modifying their regimes. In the Southern European Alps, extreme weather conditions interact with extensive land abandonment. The high flammability of vegetation seasonally threatens the wildland-urban interface. The planning and application of prescribed burning (PB) for fire hazard reduction can serve as a strategic tool to reduce landscape flammability and mitigate the post-fire erosion often observed in steep mountain relieves.

A multi-disciplinary field experiment was performed in the Italian alpine region to test the tolerance of a Scots pine (*Pinus sylvestris* L.) mountain forest, and underlying soil, to the application of low and high PB intensities. Soil health (chemical-biological properties) and plant functionality (physiology and anatomy) were monitored throughout a whole year (four sampling times). In the present work, we illustrate changes detected in the soil right after PB application (within the day).

The topsoil -at the surface of the mineral horizon- experienced average temperatures of 43° C and 423° C for low and high PB intensity, respectively. Both the intensities caused a decrease in the amount of litter (Oi-Oe horizons) and in the thickness of the organic horizon (Oa). The litter also experienced clear thermal transformations, with an enrichment in lignin and condensed aromatics in the high PB-treated sites. The organic horizon did not display similar enrichments, testifying that the heat transfer was limited.

In the mineral horizon, pH, EC and plant-available phosphorus (P) hardly changed due to PB application. Soil nitrogen (N) was mostly present in organic forms, and PB lead to an increase in ammonium. After fire, no drastic changes in the composition or trophism of soil fungi and bacteria emerged, and the minor decrease in Ascomycota observed was related to seasonal fluctuations.

With these evidences, we highlight no major concerns in applying PB -even relatively high-intensity treatments- in dry conifer forests dominated by Scots pine in the Southern European Alps.

<sup>5</sup> Centre Interdisciplinaire de Recherche sur la Montagne, University of Lausanne, Bramois/Sion, SWITZERLAND

<sup>6</sup> Institute of Biology, Division of Plant Sciences, University of Graz, Graz, AUSTRIA

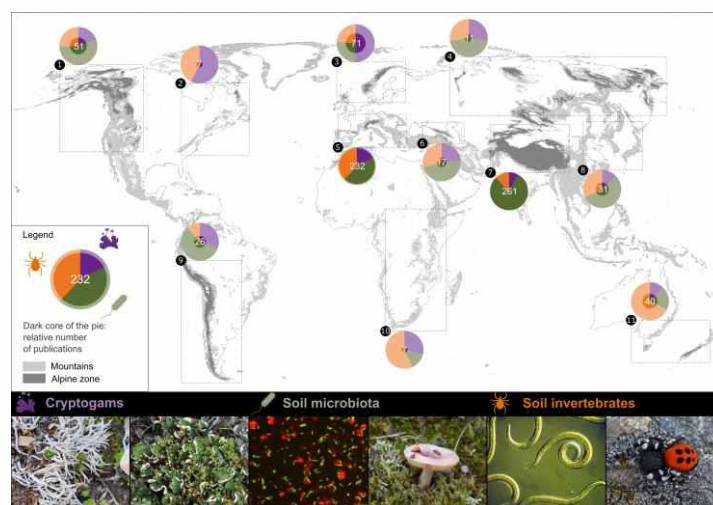

<sup>7</sup> Department of Ecology, Universität Innsbruck, Graz, AUSTRIA

Mountain soils fulfil crucial ecosystem functions and services, also for the surrounding lowland, but little is known about their soil biota diversity. Therefore, we as working group “Mountain Soil Biodiversity” of the GMBA aim to evaluate its current state of knowledge and identify future research needs.

We performed a comprehensive literature research to collate available papers focusing on biodiversity in global mountain soils above the treeline (i.e. alpine soils) for cryptogams, soil microorganisms, and soil fauna. We assessed the paper densities of eleven alpine regions, and allocated the three main taxonomic groups within them. Further, we describe what shapes diversity distribution patterns.

Alpine soil biodiversity studies are available mainly for Central Asia and Southern & Central Europe (261 and 232 papers, respectively), followed by Northern Europe (71). Therefore, many alpine regions remain widely understudied (e.g. the Andes (26) and the Caucasus (17)). Biodiversity is still high at high elevation soils, with many specialist taxa that have developed adaptations (e.g. omnivory, life under snow, and extension of life-history) to cope with the extreme environmental conditions.

We conclude that knowledge on alpine soil biodiversity is still sparse and/or not always freely accessible, especially outside Europe and Central Asia. Therefore, with our global review we bring more attention to these sensitive habitats, as they are currently threatened by climate and land-use change, but are a relevant livelihood for many people. Our review opens research questions and gives recommendations for policymakers to better understand and preserve alpine soil biodiversity, and to include these habitats in their agendas.

#### MODELLING THE EFFECTS OF THREE POST-ABANDONMENT MANAGEMENT STRATEGIES ON SOC STOCK AND WATER RESOURCES IN THE MEDITERRANEAN MID-MOUNTAINS

M. CORTIJOS-LÓPEZ <sup>1</sup>, M. MUÑOZ-ROJAS <sup>2</sup>, J. ZABALZA-MARTÍNEZ <sup>1</sup>, M. LLENA <sup>1</sup>, T. LASANTA <sup>1</sup>, E. NADAL-ROMERO <sup>1</sup>

<sup>1</sup> Instituto Pirenaico de Ecología (IPE-CSIC), ZARAGOZA, SPAIN

<sup>2</sup> Universidad de Sevilla, SEVILLA, SPAIN

Since the mid-20th century, the Mediterranean mid-mountains have been intensely marginalised, with the abandonment of rural activities. As a consequence of the advance of vegetation succession, these marginal areas have shrubbed up, with various effects on the ecosystem. On one hand, we have positive services such as the reduction of erosion, the recovery of natural ecosystems, etc. On the other, we can also find disservices such as the increased risk of fires, the loss of agro-pastoral resources or the reduction of water resources for human consumption. Soil is a fundamental agent in the regulation processes and is acquiring great relevance with regard to Climate Change due to its function as a CO<sub>2</sub> atmospheric sink. Likewise, water resources in the Mediterranean region are mostly generated in mountain areas, Thus, the research question arises: what type of management is the most appropriate for the water resources generation and the improvement of soil quality and, specifically, its carbon storage?

In the Leza Valley, La Rioja (Spain), the government has applied over the years different management measures for different purposes in these marginal areas. This baseline situation has allowed us to compare three management strategies: i) shrub clearing and agroforestry; ii) secondary succession; and iii) afforestation. Two models were used to investigate the effects of different strategies in soil organic carbon (SOC) stock and water resources: CarboSOIL and RHESSys model. Both models allow us to run different management scenarios and IPCC scenarios (4.5, most likely, was selected). The results show that all three strategies lead to an increase in the SOC stock 100 years into the future, with afforestation being of great relevance. Water flow can be increased by up to 1.52 hm<sup>3</sup> (9% monthly) when shrub clearing is applied and by up to half of this value if climate predictions are considered. These findings contribute to comprehending the soil carbon and water trade-offs in Mediterranean mountains, offering valuable insights to tailor restoration plans.

Land-use affects the critical zone, impacting the soil-plant system and related ecosystem services. The ABRESO project (Belmont Forum, CRA Soils 2020) investigates case studies of land-use change across five countries worldwide employing an interdisciplinary approach. In the case study of the Tesino Plateau (Eastern Alps, Trentino Alto Adige, Italy) socio-economic drivers of landscape change are mainly determined by land-use and abandonment cycles in response to economic and demographic pressures. Satellite data, orthophoto time series and available maps are used to study the spatial landscape changes, with particular emphasis to semi-natural grassland invasion by forest trees induced by abandonment of traditional agropastoral practices. We investigate the effects of pastures abandonment on soil-plant interaction along a transition from extensive pasture to *P. abies* forest, with an advancing *P. abies* belt. This transition was chosen as representative sub-area for ground-based investigations. Soil physical, chemical and biological properties, plant biodiversity and leaf functional traits, concentration and stable isotopes of C and N in the soil-plant system were determined. Our results reveal differences in adapting ecological strategy, resource-use efficiency and leaf economics spectrum between pasture and forest species. Managed pasture is characterized by a larger inter-specific variability in leaf functional traits, suggesting the co-presence of species with both acquisitive and conservative traits able to rely on different resource-use strategies, aligning with the niche complementary hypothesis. This alpine landscape shows high soil C concentrations (~10% at 0-10 cm depth) highlighting its potential in terms of C stocks and climate change mitigation. Pasture differs from forest in soil aggregate size and stability, N concentration and C:N ratio in soil and plants, soil enzymatic activities and microbial biomass C. These divergences highlight the impact of the pasture-forest transition on biogeochemical cycles, soil fertility and related ecosystem services. Cultural ecosystem services and stakeholders' perceptions and preferences were evaluated through socio-economic survey. Crossing natural science with socio-economic findings contributes to sustainable soil management in this alpine environment

#### INFLUENCE OF ENVIRONMENTAL FACTORS ON MICROBIAL AND ENZYMATIC ACTIVITY IN SOILS CULTIVATED WITH GUAVA IN SANTANDER, COLOMBIA

L.G. BAUTISTA-MONTEALEGRE, L.Y. DEANTONIO-FLORIDO, W.A. CARDONA, C.E. OSPINA-PARRA, J.C. LESMES-SUÁREZ, D.M. MONROY-CARDENAS, D.A. SALINAS-VELANDIA

Corporación colombiana de investigación agropecuaria - AGROSAVIA, Bogotá D.C., COLOMBIA

The common guava crop (*Psidium guajava* L.) in Colombia is of great socioeconomic importance for many farming families; this fruit is used for fresh consumption and agroindustrial processing. In the present investigation, the effect of remote environmental variables (edaphic, climatic, NDVI and altitude) on microbial activity (SAM) and dehydrogenase in soils cultivated with guava and located in three municipalities of the department of Santander (Colombia) was determined. The SAM was evaluated by measuring the absorption of CO<sub>2</sub> emitted by the microorganisms, taking four readings every 24 hours, while the enzymatic activity was determined using soluble tetrazolium salts as artificial electron acceptors. Edaphic covariates were obtained from digital layers of density, silt, clay, fragments, pH, CEC and N downloaded from the SoilGrids<sup>TM</sup> 2.0 platform (ISRIC, 2023); covariates related to quarterly precipitation volume were generated by interpolation of a raster surface using the kriging method of ArcGIS<sup>®</sup> Pro 2.9 software. 0 (ESRI), using data series from the period between 1980 and 2011 provided by AGROSAVIA, while the calculation of the normalized difference vegetation index (NDVI) was obtained from the processing of a multispectral raster of the study area captured by the Landsat 8 satellite on the platform of the U.S. Geological Survey - USGS (2023). An exploratory analysis of the data was performed using MANOVA and factorial ANOVA with Tukey's 5% test and the multivariate technique of Redundancy Analysis (RDA) was implemented to evaluate the importance of the explanatory variables on the response variables. The results revealed that both the individual factors (reading time and municipality) and their interaction had a significant effect on SMA. In addition, redundancy analysis (RDA) showed a significant effect (<0.05) of silt fraction, pH and quarterly precipitation from December to February (DJF) on SAM and dehydrogenase.

<sup>3</sup> Terrestrial Ecology Group, Institute of Zoology, University of Cologne, Cologne, GERMANY

Information on the effect of tree line shift on soil carbon (C) cycling is needed to predict the consequences of global climate change. Soil C content and C stocks may respond differently to environmental factors altered by tree-line shift. The study focuses on the assessment of C content and C stock in topsoil along mountain slopes from forest to meadow (0.1 km transects) in reserved and grazed sites of the Northwest Caucasus, Russia. In forest, meadow and their border – tree line of each slope, three points were randomly selected for soil sampling at 0-10 and 10-30 cm depth (108 samples in total). Soil C content of topsoil and subsoil increased 1.1-1.5 times from forest to meadow for both land use types, while soil C stock didn't differ significantly ( $p=0.9$  and  $0.2$  for reserved and grazed sites). The rate of decomposition of soil organic matter (basal respiration, BR) varied with soil C content ( $r=0.8$  and  $r=0.6$  for reserved and grazed sites, respectively). The relationship between soil BR and C stock was negative and weak ( $r=-0.25$  and  $r=-0.38$ ). Thus, soil C content rather than C stock determined the rates of soil processes related to soil organic matter decomposition. The temperature sensitivity of soil organic matter decomposition (Q10) and specific respiration (BR:C) didn't vary significantly along the forest-meadow transects. Thus, the tree line shift in the Northwestern Caucasus decreased soil C content, but did not affect C stocks, specific respiration and temperature sensitivity of soil organic matter decomposition.

The research was supported by Russian Science Foundation 22-74-10124.

#### INFLUENCE OF EXTENSIVE MOUNTAIN GRASSLAND MANAGEMENT IN A CLIMATE CHANGE SCENARIO

T. DANISE, S. GOLDONI, M. DAINESE, C. ZACCONE

University of Verona- Department of Biotechnology, Verona, ITALY

Assessing plant-soil ecosystem reactions to climate variability is mandatory for developing more sustainable management approaches aiming to enable both climate change adaptation and mitigation, especially in mountain areas. The main goal of the present work is to assess the impacts of both climate change and land use on the plant-soil system in extensive grasslands in terms of biodiversity and soil-related functions (e.g., carbon sequestration).

To simulate climate change, ten sites (5 meadow and 5 pastures) were identified along an elevational gradient in Trentino Alto Adige, North of Italy, and, in each site, both topsoil (0-15 cm) and plant samples were collected.

Soil samples were characterized for physical (e.g., texture, density) and chemical (e.g., pH, EC, organic carbon, total nitrogen, available phosphorous, major and trace elements, mineralogy) parameters, as well as for biological activities (by enzymatic assays, including FDAH, urease, phosphomonoesterase). Moreover, the functional traits of the 10 most abundant plant species (i.e., 70% of total cover) were measured, including different functional traits, which together describe plant physiology and leaf structure (e.g., specific leaf area, leaf dry matter content).

Preliminary results show higher concentration of organic carbon, total nitrogen and enzymatic activities in pasture compared to meadow, thus suggesting a much higher influence of soil management than climate, while plant physiology and leaf structure showed intra- and inter-specific differences with respect to both soil management and climate/altitude. Thus, the present study underlines how the resilience of extensive mountain grasslands needs to be investigated considering the soil-plant system as a whole.

This study was carried out within the PNRR research activities of the consortium iNEST (Interconnected North-Est Innovation Ecosystem) funded by the European Union Next-GenerationEU (Piano Nazionale di Ripresa e Resilienza (PNRR) – Missione 4 Componente 2, Investimento 1.5 – D.D. 1058 23/06/2022, ECS\_00000043). <sup>2</sup> University of Palermo, Palermo, ITALY

Mountain soils are characterized by greater fragility and vulnerability to climate change. The relationship between porosity, permeability, and the physicochemical interactions of soils with water are fundamental properties regulating their flows and hydrological capacities. In this study, 12 volcanic soils from a mountain grazing area in the central-southern Apennines were analyzed. The purpose of this work is to assess how the changes in thermopluviometric regimes influence the physicochemical processes associated with the movement of water and the type and pore distribution. Porosity was estimated using Digital Image Analysis (DIA) through the processing of soil thin sections of small aggregate acquired via scanning electron microscopy (SEM). 2D image reconstruction was conducted using both secondary electron and backscattered electron images allowing a porosity estimation with the Image J program. Additionally, hydrological connectivity within the soils was determined using the Fast Field Cycling (FFC) Nuclear Magnetic Resonance (NMR) relaxometry technique. The image analysis allowed the evaluation of pore sizes with diameters ranging from 2 to > 200  $\mu\text{m}$ . The following types of pores were also obtained: rounded, elongated and intermediate. Preliminary results revealed three class of pore. A prevalence of pores (90-95%) in the smaller elongated size range, ranging from 2  $\mu\text{m}$  to 15  $\mu\text{m}$  with high microporosity and asymmetric pore structure. Rounded, intermediate, and large pore was observed between 50-200  $\mu\text{m}$ . Similarly, NMR analyses of the soils confirmed three class of water molecule mobility, corresponding to the major dimensional categories of porosity estimated with DIA. The combination of SEM-EDS and free software proved to be a powerful tool for soil pore size characterization that was related with water affinity measured with NMR.

#### SMALLHOLDER INDIGENOUS AGROFORESTRY SYSTEMS IN THE NE MOUNTAINS OF TANZANIA: A PROMISING FUTURE FOR ECOSYSTEM SERVICES AND SOIL HEALTH

O.D. KIMARO<sup>1,3</sup>, D.N. KIMARO<sup>1</sup>, K. VANCAMPENHOUT<sup>2</sup>, K.H. FEGER<sup>3</sup>

<sup>1</sup> Mwenge Catholic University, Department of Agriculture, Earth and Environmental Sciences, Moshi, TANZANIA

<sup>2</sup> KU Leuven, Department of Earth and Environmental Sciences, Geel, BELGIUM

<sup>3</sup> TU Dresden, Institute of Soil Science and Site Ecology, Tharandt, GERMANY

Smallholder indigenous agroforestry systems are important components of agricultural landscapes in tropical mountains. These farming systems are important in sequestering carbon and enhancing soil fertility. However, their salient features and their potential are poorly understood and inadequately studied. Regarding the salient features, only a few studies have been undertaken focusing on the tree layer in particular the native tree species which have a multifunctional role. To better understand the nexus of multilayer smallholder indigenous agroforestry-soil-ecosystem services, our study evaluated and compared four different smallholder indigenous agroforestry systems in the NE mountains of Tanzania.

We analyzed the salient features, soil organic carbon stocks and soil fertility (proxied by effective cation exchange capacity). Results indicate that all the studied systems are multi-layered with three or four vertical layers and notable differences in their structure, composition, and diversity. The findings regarding the reported provisioning of ecosystem services (ES) show that increasing resilience and restoring the native tree species of the agroforestry systems can only be successful if knowledge of the ES potential of native species is increased, and interventions are tailored to each system's ES needs with regard to conservation and livelihood. Our findings demonstrate further that the smallholder indigenous agroforestry systems studied have a higher capacity to sequester soil organic carbon and potential for soil fertility. The multifunctionality of the indigenous agroforestry systems regarding the number of ES and the largest amount of carbon stocks in the soil contribute to the global consensus that indigenous agroforestry systems are an important strategy for climate change mitigation and adaptation. Therefore, the systems can make the smallholder agroecosystem landscapes resilient to climate change and livelihood.

THERMODYNAMICS OF NICKEL ADSORPTION FROM AQUEOUS SOLUTION ONTO HUMIC ACIDS EXTRACTED FROM PRE-OXIDIZED LOW-RANK COALS

S. OUSTAN, A. KHODABANDEH, N. NAJAFI

University of Tabriz-Soil Science Department, Tabriz, IRAN, ISLAMIC REP

The potential of low-rank coals (LRCs) in remediation of heavy metals-contaminated environments has been attracted more attention recently. Nevertheless, the LRCs generally yielded a low content of humic acid (HA) with low polarity. Therefore, there is necessary to activate them. Pre-oxidation is the most frequently used methods to do this. Further, thermodynamic studies on adsorption of heavy metals provide insights into adsorption mechanisms to modify and optimize the performance of adsorbents. In this study, three purified HAs extracted from Yazd LRC including: unoxidized (UOHA), oxidized with acidic 10% H<sub>2</sub>O<sub>2</sub> (OHAH<sub>2</sub>O<sub>2</sub>), and oxidized with two acid mixture of 3:1 H<sub>2</sub>SO<sub>4</sub>:HNO<sub>3</sub> (OHATAM), were used. The chemical characteristics of the produced HAs were determined. The batch adsorption experiments of Ni<sup>2+</sup> from solutions containing 0.05 to 0.35 mmol Ni L<sup>-1</sup> on HAs were conducted with two replications at three pH levels and four temperatures. Then, the Freundlich isotherm parameters (KF and N) were determined. Furthermore, by drawing q<sub>e</sub>/C<sub>e</sub> vs. q<sub>e</sub>, the distribution coefficient values (K<sub>d</sub>) were obtained for a dual-site Langmuir model. Finally, the thermodynamic parameters (ΔH°, ΔS° and ΔG°) were calculated from the plot of lnK<sub>d</sub> values vs. 1/T. The yield, the content of carboxyl groups and the E4/E6 ratio of the produced HAs increased after pre-oxidation process. The mean values of KF for UOHA, OHAH<sub>2</sub>O<sub>2</sub> and OHATAM were 61.64, 71.44 and 96.65 L kg<sup>-1</sup>, respectively. Pre-oxidation of LRC significantly reduced the adsorption intensity of low energy sites and increased that of high energy ones. The mean values of ΔH° for the unoxidized and oxidized HAs were 8.79 and 17.63 kJ mol<sup>-1</sup>, respectively. Furthermore, the mean values of ΔS° for the unoxidized and oxidized humic acids were 75.19 and 104.10 J mol<sup>-1</sup>K<sup>-1</sup>, respectively. The value of ΔG° for all adsorption data (except OHATAM at pH 3 and 4) was -13.30 kJ mol<sup>-1</sup>. Despite the effectiveness of pre-oxidation treatment, unexpected results were observed with increase in pH and temperature due to OHATAM dissolution.

Figure 1. Adsorption curves of Ni(II) onto unoxidized humic acid (UOHA) (A) and H<sub>2</sub>O<sub>2</sub>-oxidized humic acid (OHAH<sub>2</sub>O<sub>2</sub>) (B), at various pH and 20°C.

Figure 2. Relationship between enthalpy (ΔH) and entropy (ΔS) for the adsorption of Ni(II) onto two sites of all humic acid-based adsorbents studied (except OHATAM at pH values of 3 and 4).

#### PROJECTED IMPACTS OF CLIMATE CHANGE ON RAINFALL EROSIVITY IN NORTHEAST OF IRAN

N. GHahreman

UNIVERSITY OF TEHRAN, Karaj, IRAN, ISLAMIC REP

Soil erosion is one the major factors affecting land degradation Modeling these effects is performed using different indices among which the rainfall erosivity index is widely used which is based on rainfall intensity and energy. Global warming and climate change cause significant consequences in rainfall amount and intensity pattern especially from extreme event point of view. The current study was performed aiming investigation the effects of climate change on rainfall erosivity index in northeast of Iran (Khorasan provinces) under RCP 4.5 and RCP 8.5 scenarios, using data of a network consisting 17 synoptic stations and 25 rain gauges. Due to lack of rainfall intensity data for calculating R index, the widely accepted Fournier index (F.index) was chosen and used. The past and future period projections of rainfall (i.e. hindcasting and forecasting) of CanECM2 model downscaled by CanRCM4 regional model and also EC-Earth model till 2100 were retrieved and Fournier index was calculated using these datasets. The relation between observed and hind cast rainfall data were worked out and used for correction of future projections. The obtained values were applied for modified Fournier index calculation. The trend of these values was also examined in different time periods for each station. During the baseline period, the trend of F.index was decreasing in most of the stations. The F.index values showed higher sensitivity to rainfall amounts changes in north, northwest and western regions of Khorasan Razavi province. The future projections for synoptic and rain gauges observations were obtained from two different climate models which showed slightly different results in different regions and time periods. In general, in most of the central and southern parts of Khorasan provinces, the Fournier index showed an increasing trend in future, but in northern stations of Ghouchan, Bojnord and Golmakan a decreasing trend was observed. Further studies using other model and scenarios is recommended.

### 4. Soil health in achieving the Sustainable Development Goals 4.12 133530 - Soil degradation control, remediation and reclamation

#### THE IMPACT OF VARIABLY LAYERED AND TEXTURED TOP SOILS ON THE PERFORMANCE OF RECLAIMED SANDY LAND

M. HUANG <sup>1</sup>, N. GUO <sup>2</sup>

<sup>1</sup> Institute of Soil and Water Conservation, Northwest Agricultural and Forestry University, Yangling, CHINA

<sup>2</sup> College of Natural Resources and Environment, Northwest Agricultural and Forestry University, Yangling, CHINA

China's arable land resources are extremely scarce due to huge population, and reclaiming degraded land is effective way to increase arable land. The Mu Us Sandy Land (MUSL) is an important resource that can be partially cultivated into new arable land. Owing to scarce clay and silt particles and limited water and nutrients retention capacity, plant growth in sandy land is strongly restricted. In recent decades, various materials and methods have been adopted to improve the sandy land structure. However, challenges are still faced in searching for cheap and convenient methods to reclaim sandy land. The objective of this study was to evaluate the effect of reconstructed soil texture and layering on plant available water and consequently on plant productivity for reclaimed sandy land. Soft rock and sandy loess were used as the reclamation top soils, as well as a mixed soil with an optimized ratio of 25% soft rock and 75% sandy loess. Five layered profiles, including 30-cm soft rock (SR-S), 30-cm sandy loess (SL-S), 15-cm soft rock and 15-cm sandy loess (SR-SL-S), 15-cm sandy loess and 15-cm soft rock (SL-SR-S), and 30-cm mixed soil (MS-S) overlying 60-cm sandy soil, respectively, were packed into columns for the lab experiments of infiltration, drainage, evaporation and alfalfa growth. The available water holding capacity (AWHC) was used to identify soil water regime, while the dry biomass was used as the index of alfalfa productivity. The soil hydraulic parameters for four soils were calibrated and validated using the measured values and Hydrus-1D model was used to determine AWHC for each layered profile. The measured and simulated results indicated that AWHC values were larger for SR-S and MS-S treatments than for rest treatments, while the values of alfalfa productivity were in the order MS-S>SR-SL-S>SL-SR-S>SR-S>SL-S. The comprehensive results showed that the presence of 30-cm mixed soil overlying sandy soil would provide effective reclamation prescription to increase AWHC and plant productivity for sandy land.

#### INTEGRATED MANAGEMENT OF FARMLAND SALINITY BARRIER UNDER WATER SAVING CONDITIONS IN THE HETAO PLAIN, CHINA

J. YANG<sup>1</sup>, L. ZHANG<sup>2</sup>, W. LI<sup>2</sup>, H. HUO<sup>2</sup>, W. XIE<sup>2</sup>, C. TANG<sup>2</sup>, T. LI<sup>2</sup>, F. HUANG<sup>2</sup>

<sup>1</sup> Institute of Soil Science, Chinese Academy of Sciences; Xinjiang Agricultural University, NANJING, CHINA

<sup>2</sup> Institute of Soil Science, Chinese Academy of Sciences, NANJING, CHINA

The Hetao Plain in Ningxia, China is a region with prominent soil salinization problems in irrigation areas of western China. Water-saving demand in agricultural production makes soil salinity problem more complicated.

Field experiments of film mulching and interlayer measures were conducted in saline-alkali farmland and results showed, application of film covering increased soil moisture content of 0-10 cm by 120% compared to CK, while the soil EC was 39% lower. The interlayer measure at a depth of 40-50cm can also effectively increase the soil moisture of cultivated layer while suppressing soil salt accumulation. Compared to the traditional salt control measures, the combination of plastic film and composite barrier layer mixed with straw and water retaining agent can effectively block the upward movement of soil salt in the bottom layer and inhibit salt accumulation. At the same time, it can improve the moisture content of the cultivation layer throughout the entire crop growth period, increase soil moisture, reduce soil salinity barriers, promoting crop growth and productivity.

Field experiments of optimizing tillage and organic conditioning were carried out in saline alkali farmland and the results show, powder ridge tillage not only breaks down the hard and compacted soil in saline alkali farmland, but also makes soil particles fine and uniform, increases soil pores, and is conducive to forming a good aggregate structure. Under the conditions of powder ridge cultivation, the addition of organic materials can promote the strengthening of soil particle adhesion and effectively improve the stability of aggregates. Compared with traditional rotary tillage, the powder ridge tillage method effectively increases the proportion of larger aggregates in the soil, while the application of organic conditioning agents increases the content of larger aggregates. The combination of powder ridge and organic fertilizer application measures promotes salt leaching, inhibits the capillary rise of salt, effectively reduces soil salinity in the 0-40 cm layer, and has a significant effect on reducing severe salt alkali barriers.

<sup>3</sup> Wroclaw University of Environmental and Life Sciences-Institute of Agroecology and Plant Production, Wroclaw, POLAND

<sup>4</sup> Adam Mickiewicz University in Poznan-Department of Trace Analysis, Poznan, POLAND

The history of gold and arsenic exploitation in Zloty Stok began around the 13th century. Hundreds of years of ore mining and processing have resulted in significant contamination of water and soils with arsenic. Previous studies of Zloty Stok area were focused only in the upper part of the Trujaca river valley, where adits and ore processing facilities were located. In this study, we collected 14 soil samples along the river within the distance of 1500 m (in a straight line), in the lower course of the river. The samples were collected from the depth 0-15 cm. The pseudototal concentrations of As were determined by ICP-MS after microwave digestion in aqua regia. Potentially available forms of As were extracted from soil with 0.05 M EDTA, and actually soluble As species – with 1 M NH<sub>4</sub>NO<sub>3</sub>. The maximum As concentrations, that exceeded 8400 mg As kg<sup>-1</sup>, were found in the closest vicinity of tailings impoundment, in the upper part of the area. Those concentrations tended to decrease towards the mouth of the river, where they dropped to 1240 mg As kg<sup>-1</sup>. The percentage of easily soluble forms of As was generally low, below 1%. However, analysis of potentially soluble forms of As showed that up to 80% of the total As can be mobilized. In addition, the concentrations of As and its speciation: As (III) /As (V) /MMA / DMA, were determined in groundwater collected from five piezometers installed close to the river. For As speciation in water HPLC/ICP-MS technique were used. The maximum concentrations of As in groundwater was 225 ug L<sup>-1</sup> and exceeded permissible limit for drinking water (10 ug L<sup>-1</sup>). In all piezometers, As (III), As (V) and DMA were detected. This fact indicates that As present in the soils and water under study can pose a high risk to living organisms and to the environment.

This research was supported by the National Science Centre of Poland (2021/05/X/ST10/00680).

**Keywords:** arsenic, historical mining sites, contamination, soil, groundwater

### 4. Soil health in achieving the Sustainable Development Goals 4.12 133530 - Soil degradation control, remediation and reclamation

#### SOIL AND WATER CONSERVATION AND ECOLOGICAL CONSTRUCTION ON THE LOESS PLATEAU

H. FENG<sup>1</sup>, H. QUAN<sup>1,2</sup>, N. WANG<sup>1,2</sup>

<sup>1</sup> Northwest A&F University - Institute of Soil and Water Conservation, Yangling, CHINA

<sup>2</sup> Chinese Academy of Sciences and Ministry of Water Resources - Institute of Soil and Water Conservation, Yangling, CHINA

The Loess Plateau region, covering 640,000 km<sup>2</sup> and supporting 115 million people, experiences the most severe soil erosion in China. The efforts of soil and water conservation on the Loess Plateau can be summarized into three distinct stages: (1) control and disaster mitigation (1949–1980), (2) comprehensive management (1980–2000), and (3) ecological construction (post–2000). Main research achievements of soil and water conservation on the Loess Plateau are as follows: (1) sloping cultivated land was the primary source of human-induced soil erosion; (2) some strategies were proposed for the territorial rectification, such as 28-character strategy; (3) a theoretical and technical system for vegetation construction and restoration, a physical demonstration model for soil and water erosion control, a model for the reconstruction of degraded ecosystems, and a new model of rural revitalization based on ecological agriculture were established; (4) a scientific and technological support for the national policy of converting cultivated land back to forests and grasslands was provided; (5) the main sand-producing areas and the contribution of various measures to sand reduction was clarified. Over the past six decades, there has been a significant transformation on the Loess Plateau: (1) the vegetation index increased; (2) the sediment concentration in the Yellow River decreased; and (3) the per capita GDP increased. Therefore, compared with the past, there are greener mountains, clearer water, and wealthier people now on the Loess Plateau.

#### EFFECTS OF PYROPHYLLITE APPLICATION ON THE CONTENT OF HEAVY METALS IN LETTUCE (LACTUCA SATIVA VAR. SHANGORE)

E. SIJAHOVIC, H. CIVIC, M. TVICA, L. KARIC

University of Sarajevo- Faculty of Agriculture and Food Sciences, SARAJEVO, BOSNIA AND HERZEGOVINA

The contamination of soil with heavy metals is currently a major issue in agriculture, significantly limiting the possibility of producing safe and healthy food on such land. As a result, the remediation of contaminated soil is becoming increasingly crucial. In recent years, numerous studies have been conducted with the aim of finding suitable techniques to remove heavy metals from the soil, reducing their levels to a point that poses no threat to the environment and human health. The use of aluminosilicate material - pyrophyllite emerges as a potential agrotechnical measure in the remediation of soil contaminated with heavy metals.

The objective of this study is to determine the effectiveness of pyrophyllite in immobilizing heavy metals (lead, copper, nickel, cadmium, chromium, cobalt, manganese, iron, and zinc) and its impact on the content of essential plant nutrition elements (phosphorus, potassium, calcium, and magnesium) in both the leaves and roots of lettuce (*Lactuca sativa* L. var. Shangore). The results indicate that there was no statistically significant effect of pyrophyllite on the presence of plant nutrition elements, but there was a significant reduction in the levels of cadmium, manganese, iron, and zinc in lettuce.

**Keywords:** heavy metals, pyrophyllite, remediation

#### EFFECT OF HURRICANES IN THE SOILS OF HONDURAS

C. GAUGGEL, G. A

ASOHCSUELO, Tegucigalpa, HONDURAS

Major hurricanes and tropical storms have affected Honduras throughout its history. In recorded recent history the ones occurring in 1934, 1954, 1974, 1998 and 2020 have affected severely the soils of the country and their potential to sustain biomass generation and storage. As deforestation, cultivation on slopes with >4% gradient take place severe soil erosion and sedimentation occurs. Soil erosion rates can be in the range of 34->300 MT/ha during hurricanes (as estimated during ETA and IOTA hurricanes) and sedimentation of flood plains can reach 2 m. The effect on soil physical properties is erosion of top soils on slopes, burial of top soils in flood plains, loss of soil structure and porosity, alteration of the drainage patterns and decrease in microorganism activity, On the chemical properties, in general there is a decrease in soil pH. Cation exchange capacity, organic matter content, Ca, Mg, K and P. The impact on micronutrient content has not been clearly determined, but there is the tendency of and increase on Fe and Mn. It has been estimated that the cost of soil rehabilitation in the aftermath of these events ranges between \$20,000-35,000/ha. Rehabilitation practices include removal of sediments, liming, increase in fertilizer, crop rotation, organic matter addition (20-30 MT/ha) and deep tillage. A National Soil Conservation Program is vital for the rehabilitation and sustainability of the soils of Honduras.

#### A MODEL FOR PREDICTING TRACE ELEMENT ACCUMULATION IN SOILS – VALIDATION, SENSITIVITY, AND USE IN EXPLORING INTERNATIONAL TRACE ELEMENT FLOWS

H THOMPSON-MORRISON<sup>1</sup>, E MOLTCHANOVA<sup>2</sup>, S GAW<sup>2</sup>, B ROBINSON<sup>2</sup>

<sup>1</sup> Manaaki Whenua - Landcare Research, Lincoln, NEW ZEALAND

<sup>2</sup> University of Canterbury, Christchurch, NEW ZEALAND

Most productive land receives some application of trace element (TE)-containing soil amendments to aid production (e.g., fertilisers, pesticides, composts). TEs may be present in amendments as active ingredients (e.g., Cu-fungicides) or as impurities (e.g., Cd in superphosphate). Over time, TEs may accumulate in soils and exceed threshold levels, resulting in reduced soil fertility, and potential endangerment to food safety and the health of humans and ecosystems on which multiple Sustainable Development Goals depend (including SDG2: zero hunger, SDG12: responsible consumption and production, SDG15: life on land, and others). Simple and robust tools are needed to determine the rates of TE accumulation and inform judicious amendment application rates. We have developed a mass-balance model that uses easily parametrised input variables to produce accurate estimates of TE accumulation rates in soils. This model is not specific to any given environment, production system or individual TE, and therefore is globally applicable. To verify this, we have validated the model with data from long-term field trials and have run sensitivity analyses for a range of TEs with varying input scenarios and climate conditions. This model has been applied to oil palm plantations in Indonesia, an intensive production system on soils with naturally low nutrient levels. Our modelling has shown that soil concentrations of F and Cu can be expected to surpass threshold levels for phytotoxicity within ten years given current management practices. These findings may help to explain the high Cu concentration that is found in palm kernel expeller, a palm oil by-product, that is exported as a supplementary stockfeed. The Cu concentration of palm kernel expeller has been noted by New Zealand's dairy industry, which utilises a substantial amount of this product. Management practices therefore need to account for the import of this TE to dairy systems. This case study provides an example of how this mass-balance model can be used to explore TE fluxes in agricultural systems, and cross-boundary TE flows.

#### ENERGETIC CROPS AND COMPOST FOR THE RECLAMATION OF CONTAMINATED SOILS FROM A MARGINAL URBAN AREA IN TARANTO (ITALY) BY PHYTOREMEDIATION: CHEMICAL AND MICROBIOLOGICAL SOIL QUALITY IN EX-SITU POT TRIALS

E. BUSCAROLI, M. MAZZON, D. ALBERONI, D. DI GIOIA, C. MARZADORI, I. BRASCHI

Department of Agri-food Science and technologies, University of Bologna, Bologna, ITALY

Phytoremediation represents a highly important strategy for the enhancement and extensive management of contaminated sites. The facilities employing these technologies offer various ancillary benefits, such as employment opportunities, non-food agricultural production, urban renewal, and the creation of ecological protection areas, which compensate for the typical decontamination slowness. The plant species choice and soil preparation play a crucial role in influencing the rhizosphere ability to retain (phytostabilization), degrade, and remove (phytoextraction) contaminants. The use of amendments, compost, or manure can alter the solubility of contaminants, support microbial activity, and promote plant growth. Positive interactions between plants and soil microbiota are known to enhance nutrient uptake and improve tolerance to stress caused by pollutants.

In this study, Brassica juncea and Sorghum bicolor, energy crops employed in biomass production, were tested in ex-situ pot trials to assess the remediation potential of soil contaminated with polychlorinated biphenyls (PCB), heavy hydrocarbons, polycyclic aromatic hydrocarbons (PAH) and trace elements (Cu, Sn, Pb and Zn). Two different compost amendments were tested as biostimulant conditioners. At the end of the trial, the effect of different plant and compost combinations on pollutant removal, soil biochemical indicators, microbial composition, and biomass production were evaluated.

The results highlighted that adding compost increased the biomass of both plant species, although it slowed down the degradation of heavy hydrocarbons. Moreover, compost addition partially improved microbial biomass carbon (MBC) and altered soil microbiota composition and diversity, especially favoring Sphingomonadaceae and Nocardioideae to the expense of Bacillaceae. Finally, the presence of compost promoted the biomass yield of Sorghum, indirectly contributing to higher absolute removal and translocation of Pb and Cu.

Experimental evidence indicated that the choice of plants and the use of amendments have a significant impact on soil quality and microbial communities, as well as on the overall success of the phytoremediation, since it heavily relies on economic (biomass) and social outputs as the soil remediation per se is extremely time-consuming.

**Keywords:** Phytoremediation, Persistent Organic Pollutants, Potentially toxic elements, Soil microbiota, Biomass crops

#### ENVIRONMENTAL PERSISTENCE AND FATE OF NEONICOTINOIDS INSECTICIDES IN BELGIAN AGRICULTURAL SOILS

M BURON <sup>1</sup>, E FOGUENNE <sup>1</sup>, A BLONDEL <sup>2</sup>, P DEFOURNY <sup>1</sup>, A JACQUEMART <sup>1</sup>, J RADOUX <sup>1</sup>, L JEANNEROD <sup>1</sup>, Y AGNAN <sup>1</sup>

<sup>1</sup> Earth and Life Institute, UCLouvain, Louvain-La-Neuve, BELGIUM

<sup>2</sup> Walloon Agricultural Research Centre, Gembloux, BELGIUM

With the intensification of agricultural practices including the use of insecticides, a large proportion of pollinator species have seen their population decrease for a few decades. Thus, it is important to identify the underlying mechanisms of this pollinator decline for conservation purposes and maintaining healthy ecosystem services. Among common insecticide, neonicotinoids are high toxicity products for invertebrates that represented a 25% share of the global insecticide market in 2010. Due to their remanence and extended persistence in the soil, neonicotinoids pose a strong lasting risk for the ecosystem. Our project aims to assess the occurrence and persistence of neonicotinoids in the soil and identify the environmental factors that control neonicotinoids dynamics at the landscape scale. We measured concentrations of seven molecules of neonicotinoids in the top 30 cm of soils along different agricultural landscapes and crop rotations, in 83 samples representing 45 crop sites in Belgium. Our results showed concentrations of clothianidin and imidacloprid  $>0.5$  ng kg<sup>-1</sup> for 72 and 52% of samples measured, respectively, and up to 16.3 and 6.4 ng kg<sup>-1</sup>, respectively. Highest concentrations were found in beet and vegetables-legumes rotations. Surprisingly, both compounds were detected (i.e.,  $>0.2$  and  $>0.4$  ng kg<sup>-1</sup>, respectively) in ca. 50-60% of grassland soil samples. Highest concentrations were not especially reached for samples where beet was recently grown. These results will allow further modeling of the assessment of potential pressures on pollinators using landscape and crop rotation data in Belgium. This work has the intent to better understand the trajectory of neonicotinoid-based insecticides within landscapes and to greatly contribute to future conservation and agricultural landscape decisions in Belgium.

#### DESTRUCTIVE IMPACT OF MILITARY ACTIONS ON THE CHERNOZEMS OF UKRAINE

V. LEBED, V. SOLOVEY, Y. ZALAVSKYI, S. BALIUK, M. SOLOKHA, A. KUCHER, A. LEVIN

National Scientific Center «Institute for Soil Science and Agrochemistry Research named after O.N. Sokolovsky», Kharkiv, UKRAINE

Ukraine has significant soil resources that have been and are being damaged by Russian Federation's armed aggression against Ukraine. This has a negative impact not only on the food security of the country, but also of the entire world. The largest part of Ukraine is presented by 'black soils', namely Chernozems. National Scientific Center «Institute for Soil Science and Agrochemistry Research named after O.N. Sokolovsky» has accumulated experience in researching the impact of military actions on soils and assessing soil damage.

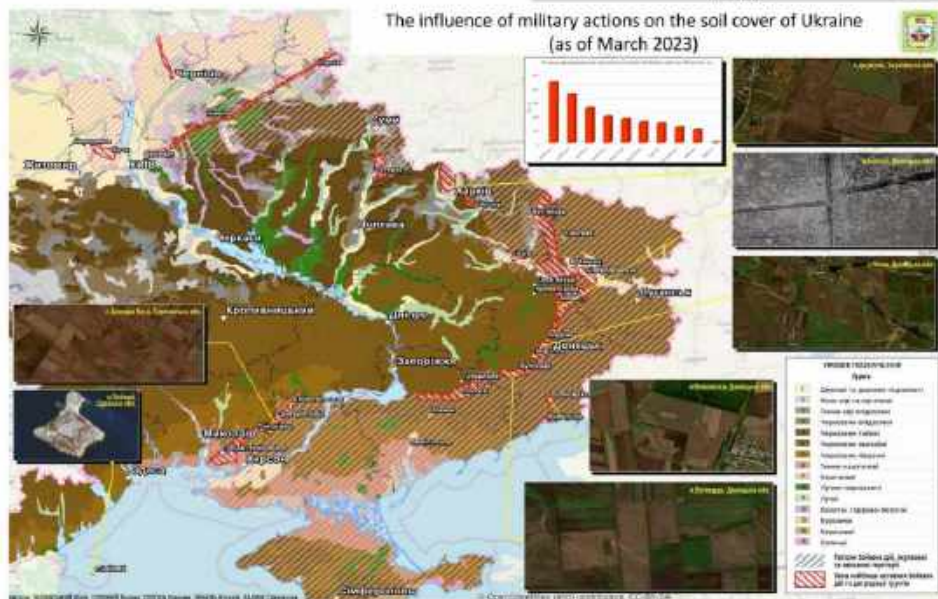

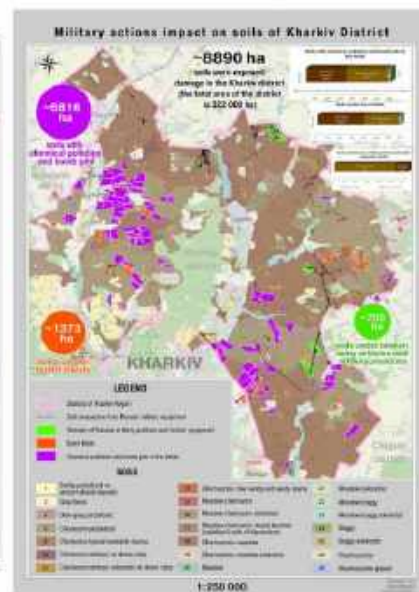

For today, the application of the traditional field survey of soils is complicated by the intensive battles or occupation of the territories. Therefore, it is necessary to widely use remote methods for researching the damaged soil cover. For the first time, was used and analyzed the images from Sentinel-2 satellites. This is the first, expert stage for assessing military degradation before refinement by field survey.

A total of 17 main kinds of military soil degradation were identified with a corresponding evaluation system according to the degree of manifestation with clear quantitative criteria according to the parameters of soil property changes. The Instruction on sampling of war-damaged soils was developed, the classification and assessment system of damaged soils was improved. Based on the soil maps and satellite data with selective verification by field survey, the maps of the impact of hostilities on the soils at the national, regional and local levels were created. They were used to display damage areas, assess condition of soils and calculate damages. At framework of the National Research Foundation Project, we started remote and field (after demining) survey the lands of Chkalovska community, where the zones of the greatest influence of hostilities were identified.

The amount of damage and losses caused to lands and soils of Ukraine as of February 24, 2023 was preliminarily calculated based on several indicators. The total amount of damage is estimated at 34 billion dollars and continues to grow.

# ORAL PRESENTATIONS

Type of degradation	Subtype of degradation	Kind of degradation
Mechanical	Military	Decreasing profile depth
		Reducing of humus content
		Formation of craters, trenches, pits
		Embankment formation
Physical		Anthropogenic skeletal structure
		Deterioration of physical properties
Chemical		Stable changes in the granulometric composition
		Contamination with inorganic substances
		Contamination with toxic inorganic substances
		Contamination with toxic organic compounds
Physical and chemical		Pyrogenic change in the content of nutrients
		The depth of the first salt horizon from the surface
Biological	Acidification, alkalization	
	Degree of salinity of the upper meter layer	
	Soil toxicity	
		Reduction of soil biological activity
		Reduction (narrowing) of biodiversity

The aim of the project Transforming Unsustainable management of soils in key agricultural systems in EU and China - Developing an integrated platform of alternatives to reverse soil degradation (TUDI) is, by others, to develop a set of decision support tools (DST), to assess soil health, based on simple on-site analyses. DSTs will be directly linked to the catalog of integrated control measures, practices and strategies, to prevent soil degradation for healthy soils and/or to start the effective remediation process for degraded soils.

The catalog will be structured according to individual characteristics of potential soil degradation processes by agricultural use (soil erosion, soil compaction, organic carbon content, soil biology, nutrient content and management, etc.) and will lead users according to the result of soil health analyses, through individual types of measures and practices. They will be characterized by definition, but also by principles and aims. Information about necessary technology, equipment, costs and efficiency, same as linking to EU and national policy and subsidy support are also included.

The catalog technically is linked to digital DSTs, where links to WEB and also PDF version can be found. Based on the result and classification of the soil health survey, the cluster of the most effective measures/practices is recommended, pre-selected and displayed. The user can then pick the most suitable ones for given conditions, and estimate efficiency and costs, based also on the state subsidy system. Also to select the optimum combination to maximize positive and synergy effects.

The catalog will be available in English, Chinese and in national languages of TUDI project states (Spain, Czech Republic, Austria, United Kingdom, Hungary, Bulgaria, Italy).

The structure, types of measures/practices, content and applicability of the tool by users will be presented at the congress.

This research has been supported by H2020 project TUDI - No.101000224

#### REMEDIATION OF CADMIUM CONTAMINATED PADDY SOIL WITH A GIANT RICE

Q. WU, C. CHEN, Z. WEI

South China Agricultural University, Guangzhou, CHINA

Typical Cd hyperaccumulators are generally small and rather difficult to be cropped for phytoextraction. This study aims to identify the accumulation characteristics of Cd by a newly-developed giant rice and use this high biomass crop to remediate Cd contaminated soils. Soil column and lysimeter tests were conducted with giant and normal rice under different water conditions. The Cd accumulation in rice, chemical speciation and subcellular fraction in roots were examined. In column test, grain Cd concentration of giant rice was only 0.006 mg/kg under sustained flooding. However, the Cd concentration increased to 0.547 mg/kg under the semi-dry condition (drained after tillering stage). Cd content in giant rice straw and root was significantly higher than that of normal rice (cv. Simiao). By keeping soil moist after tillering stage in the lysimeter tests, Cd content in giant rice grain were 0.015~0.034 mg/kg. The translocation factor from root to straw and from root to grain were lower than those of Simiao rice under all water conditions. Concerning Cd in root, 37.9% was trapped on the root surface, 44.5% was fixed in the root cell wall, and only 17.6% entered the endoplast. The iron plaque content of giant rice root was 1.33 times of that Simiao rice and fixed 63.2% Cd on root surface. In addition, under semi-dry condition, the Cd phyto-extraction amount by the giant rice shoots was 269 ug/plant, and the phytoextraction efficiency of one crop were 4.81% of Cd in topsoil. The decrease rates of total and CaCl<sub>2</sub>-extractable Cd were 10.8% and 40.1%, respectively. Therefore, giant rice is an excellent cultivar with low Cd accumulation in grain, and under semi-dry condition, giant rice has a good Cd phyto-extraction ability. A production/remediation mode with early giant rice for normal production and a regenerated late giant rice for phytoremediation was then proposed, showing that the regenerated late giant rice under semi-dry condition do have a rather high Cd phytoextraction by shoots.

#### THE APPLICATION OF OLIVE POMACE DIGESTATE TO THE SOIL PROMOTES THE SORPTION OF PESTICIDES AND THE GROWTH OF THE LIGNINOLYTIC FUNGUS PLEUROTUS ERYNGII

N. COLATORTI, G. MAZZIOTTA, E. LOFFREDO

University of Bari-Department of Soil, Plant and food sciences, Bari, ITALY

New products and byproducts are released from the technological conversion of waste biomass for bioenergy production. Due to their high organic carbon content, these materials, when used as soil amendments, can improve the overall quality and fertility of the soil. In a study carried out within the framework of the Agritech National Research Center Project funded by the EU, Next-GenerationEU (PNRR) – M4C2 Inv.1.4, we explored the potential of an innovative solid digestate (DG) obtained exclusively from two-phase olive pomace to regulate some chemical and biological processes that occur in a loam soil. The DG was characterized using several analytic techniques, such as SEM-EDX and FTIR techniques. In batch-type adsorption tests, the retention of the fungicide boscalid and the herbicide oxyfluorfen on non-amended soil (na-S) and soil amended with 1% (S-DG1), 3% (S-DG3) and 6% (S-DG6) DG (w/w) was quantified and modelled using the theoretical equations of Henry, Freundlich and Langmuir. At 20 °C, KF values of na-S increased significantly after the addition of DG, especially at the highest dose, being the increases of S-DG1, S-DG3 and S-DG6 of 84, 83 and 185% for boscalid and 2, 2 and 194% for oxyfluorfen, respectively. Hysteretic desorption of both molecules was observed from all samples, especially S-DG6. *Pleurotus eryngii* is an important soil-resident fungus involved in the soil carbon cycle due to its enzymatic equipment. In lab-scale experiments, the fungus was exposed to 0.02 and 0.1% (w/w) DG alone or preliminary interacted with 100 mg L<sup>-1</sup> soil humic acid (HA). The latter treatments were adopted to simulate field conditions where DG likely interacts with the native organic matter of the soil. All treatments, especially DGO.1%-HA, significantly promoted the mycelium growth rate. In conclusion, the overall results obtained indicated that the addition of DG to soil can exert important effects, such as the control of the bioavailability of pesticides in soil and the stimulation of beneficial fungi.

#### THE EFFECT FIELD WHEELING OF ON SOIL WATER RETENTION AND ABOVE GROUND PART OF MAIZE DURING A GROWING SEASON IN NORTHEAST CHINA

X. HUANG <sup>1</sup>, H. WANG <sup>2</sup>, L. WANG <sup>3</sup>, R. HORN <sup>4</sup>, T. REN <sup>5</sup>

<sup>1</sup> Henan University of Technology, Zhengzhou, CHINA

<sup>2</sup> China Agricultural University, Beijing, CHINA

<sup>3</sup> China Agricultural University, Beijing

<sup>4</sup> Christian-Albrechts-University Kiel, Kiel, GERMANY

<sup>5</sup> China Agricultural University, Beijing, CHINA

With the use of heavy machinery, soil compaction induced by wheeling process on farmland has become a serious problem in recent years of China. In this study the effects of wheeling on soil water retention and the above ground part of maize were revealed. The results showed that field soil gradually deformed with the increase of wheeling frequency. The vertical settlement after wheeling with 1, 3, 5, 21 passes (C0, C1, C3, C5, and C21) were 6.4 cm, 8.0 cm, 9.5 cm, and 13.7 cm, respectively. The wheeling increased soil volume water content and reduced the soil matric suction, and this effect lasted for the whole growing period of maize in 2019. The fluctuations of volume water content with rainfall events under C21 treatment were not so obvious compared with those of C5 and C0 treatments. In heavy compacted soils under C5 and C21 treatments, soil shrank more and cracks were easily formed during dry period, and during the wet period water logging lasted in longer period compared with C1 treatment. With the increase of wheeling passes the total areas of cracks and duration of water logging gradually increased, respectively. The wheeling showed cumulative effects on reducing the above ground part of maize. Except maize height all the above-ground parameters of maize showed significant decreases when soil was permanently compacted (C21) by wheeling. Additionally, compared with maize parameters of height, stem diameter, leaf biomass per plant, and 100-grain weight, the wheeling effect was more obvious on the above-ground biomass per plant and yield. Wheeling after 1, 3, 5, and 21 passes on soil, the above ground biomass per plant of maize decreased by 14.5%, 36.9%, 37.0%, and 56.4% with yield losses of 9.7%, 30.7%, 38.4%, and 59.7%, respectively. Therefore the traffic load and frequency should be strictly controlled in order to mitigate the harmful effect of compaction and shearing on soil and maize.

#### EFFECTS OF RESIDUAL SLUDGES ON THE PHYSICOCHEMICAL PROPERTIES OF A DEGRADED AGRICULTURAL SOIL UNDER TUNISIAN SEMI-ARID CLIMATE

S. BEN HADJ MBAREK <sup>1</sup>, F. M LAIKI <sup>1</sup>, A. TLILI <sup>1</sup>, R. ATTIA <sup>2</sup>, I. DRIDI <sup>1</sup>

<sup>1</sup> University of Tunis El Manar, Faculty of Sciences of Tunis, Department of Geology, Tunis, TUNISIA

<sup>2</sup> Direction Générale de l'Aménagement et de la Conservations des Terres Agricoles (DGACTA), Tunis, TUNISIA

The soils of arid and semi-arid regions are relatively poor in organic matter. The intensification of the agricultural practices, the light texture of these soils, and the non-return of crop residues to the soil accelerate this impoverishment. To improve the fertility and productivity of these soils, the application of organic amendments becomes indispensable. Among these organic fertilizers, residual sludges can potentially serve as an amendment, mainly for soils in arid regions.

In this context, we conducted a spreading trial of residual sludges on a clay loamy degraded saline soil of an agricultural plot situated in Foussena-Kasserine (Central West of Tunisia). The studied plot has an area equal to 4,22 hectares, and was treated with two doses of dry powder sludge 5 Ton/h. The soil sampling was carried out from February to July 2023. The selected control soil has a slightly alkaline pH = 8, high Electrical Conductivity (CE = 16 mS/cm) and low organic matter, not exceeding 1%. Following six months of sludge spreading, five samples were taken at a depth of 30 cm. After spreading, the results showed significant improvements in several soil properties. Indeed, there was a notable increase in the percentage of assimilable phosphorus, exemplified by values escalating from 5,6 ppm to 57,2 ppm. Furthermore, organic matter content showed an enhancement compared to the control, with values rising from 0,78% to 2,29%. The level of certain metals, including lead, zinc, iron, and nickel, showed also significant increases, while remaining well below the standards. However, a slight decrease in pH was noted in the amended soils, with pH values declining from 8 to 7.

These findings highlight the significant potential of using residual sludge as organic fertilizer, offering a method for reusing organic waste materials beneficially. This practice helps reduce the volume of waste directed to landfills or incineration while simultaneously fostering improvements in soil fertility and promoting plant growth.

### 4. Soil health in achieving the Sustainable Development Goals 4.12 133530 - Soil degradation control, remediation and reclamation

#### EFFECT OF PHOSPHOGYPSUM ON SOIL PHYSICO-CHEMICAL PROPERTIES IN TUNISIAN SALT-AFFECTED SOILS

W. MEZLINI<sup>1</sup>, A. BENEDUCI<sup>2</sup>, S. CHAKRABORTY<sup>3</sup>, R. BEN AMOR<sup>1</sup>

<sup>1</sup> University of Tunis El Manar, Department of Geology, Faculty of Sciences of Tunis, Tunis, TUNISIA

<sup>2</sup> University of Calabria, Department of Chemistry and Chemical Technologies, Rende, ITALY

<sup>3</sup> 3University of Calabria, Department of Ingegneria Modellistica Elettronica & Sistemistica, Rende, ITALY

Salinity is one of the most challenges for soil fertility, agriculture production and crop in arid and semi-arid regions, such as large area of Tunisia, soil affected by salts occupy an area of 1.5 million hectares, about 10% of the total area of the country. Therefore, Phosphogypsum (PG) could be a promising amendment to reduce the salinity affect and improve physico-chemical soil quality in salt affected soil. The present study aimed to evaluate the effect of PG on soil salinity and physico-chemical proprieties of soil collected from agriculture irrigated area in West Central of Tunisia. The treatment consisted of different rates of PG, PG+Manure (10t/ha PG, 20t/ha PG, 40t/ha PG, 10t/ha PG+Manure, 20t/ha PG+Manure, 40t/ha PG+Manure, Soil+Manure). The results revealed that PG application improve soil structure by promoting flocculant action by calcium, positive effect of PG on other soil physical properties (soil hydraulic properties, total porosity, and bulk density). Compared to results revealed before amendment with PG, Electrical Conductivity (EC) was decreased from 14.49 mS/cm to 2.26 mS/cm in soil treated with 20t/ha PG+Manure, a clear decrease in pH values from 8.089 in soil without amendment to 6.96 in soil treated with 40t/ha PG+Manure. we noted an increase in the level of Organic Carbon (OC) which went from 3.27% in soil without any treatment to 4.79 in soil amended with 20t/ha PG+Manure to 5.17 in soil amended with just manure (1kg of manure in m<sup>2</sup>). This study supports the use of PG as an amendment for reclaiming salt-affected soils through monitoring agronomic and environmental impacts, but also the monitoring of other PG compounds (heavy metals, radioactive elements) is essential, so despite the importance of the results obtained in relation to salinity, advanced research studies must be carried out.

**Keywords:** soil salinity, soil sodicity, physico-chemical properties, PG amendment

<sup>3</sup> Centre de Cooperation Internationale em Recherche Agronomique pour Le Développement/CIRAD, Montpellier, FRANCE

<sup>4</sup> BRAZIL

Sewage sludge (SS) is a good soil amendment, due its high contents of organic matter and mineral nutrients. Reapplication of SS is a way to increase its disposal and at same time improving even more the soil fertility and its biological properties. This is particularly important for recovery of degraded soils, which requires large nutrient inputs to promote plant growth. Arbuscular mycorrhizal fungi are relevant in soil microbiota, being an indicator of soil biological activity. We aimed to assess the effects of SS reapplication on soil properties. In 2005 we conduct an experiment on sandy, impoverished and degraded soil in Southeastern Brazil, where rates of SS (2.5; 5; 10; 15; 20 Mg ha<sup>-1</sup>) and mineral fertilization (as recommended by literature) were utilized as treatment for soil recovery, as well a control without any intervention. Native tree species from Atlantic Forest biome were planted for vegetation cover. In 2016 the same treatments were reapplied in the area, but at this time we used composted SS at different rates (10; 20; 30; 40; 50 Mg ha<sup>-1</sup>). After four years we investigated its effects on soil fertility (moisture and mineral nutrients) and mycorrhizal status (root colonization and sporulation) at wet and dry season. The higher rates of SS application increased the contents of P, Ca, Mg, Cu and Zn in the soil. Independently of rate, the soil treated with SS had higher moisture, at both wet and dry seasons. This results reinforce the value of SS for use in soil recuperation and vegetation growth. The SS treatments resulted in root mycorrhizal colonization being 18% higher than mineral fertilization, with no difference between seasons. At dry season an increased sporulation was observed at control soil, possibly due grasses favored by reduced tree growth in this soil. By other hand, at wet season the sporulation was higher under the 50 Mg ha<sup>-1</sup> rate, suggesting complexity on the factors controlling mycorrhizal ecology on soil.

#### EFFECT OF INCREASED SOIL SEALING EXTENT ON INCREASED RUNOFF ACROSS TWO SUBURBAN CATCHMENTS IN NORTHEAST SCOTLAND; COMPARISON OF COPERNICUS LAND MONITORING SERVICE AND BRITISH ORDNANCE SURVEY DATA

A. SHARIFIFAR, N. BAGGALEY

Department of Environmental and Biochemical Sciences, the James Hutton Institute, Aberdeen, UNITED KINGDOM

Soil sealing can be defined as the destruction or covering of the ground by an impermeable material, which is directly associated with the degree of urbanisation. It is a major cause of soil degradation which often affects fertile agricultural land, puts biodiversity at risk, increases the risk of flooding and contributes to global warming. Additionally, polluted runoff is an effect of soil sealing which threatens water resources and degrades productive lands. In this study, two catchments with a total area of 3395.5 km<sup>2</sup> around Aberdeen city in northeast Scotland were investigated as part of a project to evaluate socio-economic costs of land degradation and its effects on water resources. An evaluation of soil sealing extent change from year 2009 to 2018 and 2023 was conducted using Sentinel satellite images (Copernicus Land Monitoring Service of the European Union) and the British national Ordnance Survey (OS) MasterMaps® data for impervious surfaces. The study showed that the British OS maps can provide more accuracy and precision of details with less uncertainty of interpretation of imperviousness by providing higher spatial and temporal resolution in sealing maps. The impervious surface extent in the whole catchment (considering two sub-catchments) has increased from 49.3 km<sup>2</sup> (in 2009) to 59.2 km<sup>2</sup> (in 2023). The distribution and extent of sealed surfaces has impacted the expected runoff percentage. A high-resolution soil series map with associated Hydrology of Soil Type (HOST) classes overlaid with the imperviousness map of the study area was used to infer weighted standard percentage runoff for the catchment in 2009 and 2023. Then, we calculated the change in expected runoff using an urbanisation adjustment index. The results showed a 0.6% increase in the total weighted standard percentage runoff for the catchment. Outcomes of this study help with suitable urban and rural land use planning and design.

Dedicated crops represent an important feedstock to decarbonise the energy sector and to meet the no net emissions of greenhouse gases by 2050, as set by the European Green Deal. However, the greenhouse gas performance of biomass to energy can be negatively impacted by Indirect land use change (ILUC) effects. In fact, the increasing demand for biomass, increases the competition for land, threatening food security. Consequently, cultivation of industrial crops on contaminated land is repeatedly suggested as an approach to minimize land use competition with food crops and land use change controversies.

GOLD project (Bridging the gap between phytoremediation solutions on Growing energy crops on contaminated Lands and clean biofuel production) aims to produce clean low Indirect Land Use Change biofuels by growing selected lignocellulosic crops on contaminated land, and, in long-term, to return the polluted lands back to the agricultural production. Therefore, the objective of this work was to identify opportunities and constraints associated with the cultivation of miscanthus and switchgrass in contaminated soils. Effects of the cultivation of those crops in the contaminated soils were addressed towards impact on soil (nutrient status, soil properties, erosion). Results suggest that these perennials accumulate higher soil organic matter and provide structural enhancement, due to the continuous permanence in the soil, high inputs of residues and vigorous root development. Also, these crops are low input crops (e.g. fertilizers) and therefore a less intensive soil amendment is in place, contributing to minimize impacts and to lower pH variations. Concerning the erosion, these perennials reduce the risk due to the greater surface coverage over a long period of time, the continuous presence of an underground biomass and the greater interception of rainfall. Although yields are affected by the level of contamination, crop management options, such as the use of plant-associated microorganisms and a variety of bio-stimulants may reward the impact on the soil quality index, by greater reduction of soil contaminants.

<sup>4</sup> Institute Tunis El Manar, Institute of Veterinary Research of Tunisia, Tunis, TUNISIA

Pentachlorophenol (PCP) is a recalcitrant compound that could persist in the environment causing serious pollution concerns. Bioremediation of PCP is demonstrating to achieve encouraging results compared to the common physical and chemical techniques.

The aim of this work was to assess different bioremediation processes as biostimulation and/or bioaugmentation approaches of artificially PCP (100 mg kg<sup>-1</sup>) contaminated forest soil (Sc). The biostimulation treatment provided phosphate and three different organic amendments, such as forest compost (FC), municipal solid waste compost (MC) or sewage sludge (SS). Two different microbial consortia B1 and B2 were used as bioaugmentation treatments. The combination of both biostimulation and bioaugmentation techniques was also assessed. Soil physical and chemical properties, PCP amount, soil microbial biomass carbon, soil respiration and some enzymatic activities at zero time (T0) and after 30 d incubation (T30) were evaluated.

No significant changes in terms of main chemical soil properties were observed, but an increment of organic carbon in all organic amendment-based treatments at T0 and T30 was observed. The PCP concentration at T0 was on average 82 mg kg<sup>-1</sup> in all soil samples. After 30 days natural attenuation was responsible for the reduced PCP extractable in Sc (68.5 mg kg<sup>-1</sup>). The combined action of biostimulation and bioaugmentation led to a strong PCP reduction (71%) in Sc+B1+FC sample, whereas a depletion of only 52% and 41% occurred with the single application of FC or B1, respectively. The presence of PCP negatively affected soil microbial biomass carbon and the activity of dehydrogenase and fluorescein diacetate hydrolysis that recovered upon organic amendment also combined with microbial consortia B1 or B2. FC based biostimulation treatment also stimulated soil respiration. These results demonstrate that the simultaneous treatment of biostimulation and bioaugmentation showed a better performance in the PCP removal with more effectiveness than the single techniques.

#### LEARNING BY DOING IS MORE MEMORABLE: SOIL JUDGING AS AN EDUCATIVE TOOL IN NEW ZEALAND

C SMITH<sup>1</sup>, S CARRICK<sup>2</sup>, J NELSON<sup>1</sup>, J MAZZETTO<sup>1</sup>, V PENNEY<sup>2</sup>, R MCLENAGHEN<sup>1</sup>

<sup>1</sup> Department of Soil and Physical Sciences, Lincoln University, Lincoln, NEW ZEALAND

<sup>2</sup> Manaaki Whenua Landcare Research, Lincoln, NEW ZEALAND

Soil scientists are increasingly working in a multidisciplinary world where they interact with professionals from different disciplines and diverse end user groups. The ability to communicate, and to be an effective team player are just as important skills as the ability to apply practical field skills and describe soil profiles. The kinaesthetic approach embodied in soil judging allows the student to also connect with pedological theory; and it is a pedagogically aligned style of learning.

At Lincoln University we first adopted innovative, experiential learning in the form of soil judging in 2016 to address these issues, and have worked collaboratively with the a Crown Research Institute in New Zealand (Manaaki Whenua Landcare Research) to develop this programme. Soil judging in New Zealand is in its infancy compared to other countries, but the undergraduate student soil science society and academic staff have been enthusiastic in practising soil description skills and land use interpretation, participating in soil judging contests in New Zealand and Australia.

Students report that they have become more confident in soil description and that it has stimulated their interest in learning about soil science. We designed a micro credential to recognise the academic work of the students. Several soil judging graduates have secured employment as pedologists at Crown Research Institutes or as soil resource specialists in local / regional government organisations. Soil judging may also be an effective recruitment pipeline into the discipline: offering those students with a practical and kinaesthetic aptitude who perform well at soil judging an insight into the academic side of the soil science discipline. We posit that soil judging competitions are an effective framework for students to acquire a valuable range of practical, field-based skills for a professional career in soil science or allied enterprises.

#### SIMPLE EXPERIMENTS PERFORMED IN THE SCHOOL YARD TO UNDERSTAND ECOLOGICAL SOIL FUNCTIONS: CELEBRATING A DECADE OF THE OUTREACH PROGRAM "TERRAMÓVIL"

C SIEBE<sup>1</sup>, A C LOPERA GASCA<sup>1</sup>, I.T. LARA MONTIEL<sup>2</sup>

<sup>1</sup> Universidad Nacional Autónoma de México, Institute of Geology, Ciudad de México, MEXICO

<sup>2</sup> Universidad Nacional Autónoma de México, Posgrado en Ciencias de la Tierra, Ciudad de México, MEXICO

In 2013 the Institute of Geology of the National Autonomous University of México (UNAM) started the outreach program "Terramóvil" to promote Earth Sciences among children and adolescents and to provide teachers with tools to enforce

- a) the protection from natural hazards
- b) the importance of soil functions and conservation
- c) the understanding of Global Climate Change

Terramóvil has designed sets of simple experiments carried out in the school yard, to learn by active participation about the different processes that govern the dynamics of our planet and the evolution of life. Each set of 4 to 5 experiments is designed to cover a specific topic during a regular school class. The children are divided in groups of maximum 15 to allow hands-on participation of all. All sets of experiments are linked to the local situation in order to promote awareness on how the personal life and surrounding of the participants is affected or involved. The different sets of experiments are adapted to the study plans of primary, secondary or high school education and thus foster the learning process and provide teachers with ideas on how to make the topics more accessible and attractive. Soil and its functions unfortunately is not explicitly considered in the study plans, but our activities show teachers where in the study plan soil knowledge is indispensable. The school visits are conducted by the person leading the outreach program and who is contracted by the university. Additionally bachelor students of Earth Sciences, Natural Sciences or Geography are recruited mostly as volunteers and up to five by offering a small scholarship. The students profit from the outreach project, since they learn how to translate specialized language into more simple words, improve pedagogical skills, and experience that their knowledge is appreciated and useful.

The strategy of the Terramóvil will be presented with examples and the 10-year experience of the project summarized.

#### INCREASE SOIL AWARENESS AMONG PUPILS, STUDENTS, AND THE GENERAL PUBLIC IN AUSTRIA

M WOHLMUTH <sup>1</sup>, B BIRLI <sup>2</sup>, C B FOLDAL <sup>3</sup>, A WAWRA <sup>4</sup>, M ENGLISCH <sup>3</sup>, S HUBER <sup>2</sup>, S SCHWARZ <sup>5</sup>

<sup>1</sup> University of Natural Resources and Life Sciences, Vienna, AUSTRIA

<sup>2</sup> Environment Agency Austria, Vienna, AUSTRIA

<sup>3</sup> Federal Research Center for Forest, Vienna, AUSTRIA

<sup>4</sup> Austrian Agency for Health and Food Security, Vienna, AUSTRIA

<sup>5</sup> Austrian Soil Association, Vienna, AUSTRIA

In order to increase awareness and understanding of the importance of soil, the ASSS, the Austrian Soil Science Society, together with other relevant Austrian institutions has developed concepts and materials and initiated a series of workshops to familiarise students and the general public with the importance of soil.

One format is the workshop series Boden macht Schule, a series of activities for children between the ages of nine and thirteen. To suit the situation in the classroom and to involve every child in the activities, the workshop comprises four stations with practical activities. Key elements include observing and identifying soil animals, simple science experiments and rummaging in the soil. Pupils and students are encouraged to use all their senses and touch, observe, smell, and listen to soil. Experiments include i) a filter experiment, ii) defining the texture of soil by touching it and iii) working with microscopes and binoculars. The children are asked to carry out the tasks themselves. At least 15 workshops are held in Vienna every year and are very popular with teachers, pupils and students.

National projects such as BOKLI and Futuresoils had the format of scientists working with students aged 10-14 for a whole year. In these projects, they learnt about the relationship between soil and climate and/or food production. Following a scientific approach, students collected and observed various parameters and learnt to grow, nurture and harvest vegetables and herbs in and outside their classroom.

In 2023, Soil talks - a project aimed specifically at initiating exchange in between young and retired persons was carried out. In Soil Talks these groups were introduced in soil health through workshops, interactive lectures, and walks.

Other activities include a regular Soil Festival on the premises of the Federal Forest Research Centre, as well as participation in events and presentations at the Vienna Zoo and regional thematic activities.

We also offer training workshops for key groups in environmental education.

#### RAISING SOIL AWARENESS: A HOLISTIC APPROACH TO SOIL EDUCATION IN ESTONIA

A. ASTOVER, A. KUU, M. SUTRI, K. NURME, E. REINTAM, M. SHANSKIY

Estonian University of Life Sciences, Tartu, ESTONIA

Awareness of the importance, diversity and multi-functionality of soils is a prerequisite for sustainable development. Although traditional soil science teaching has been in university programs for more than 100 years in many countries, there is a need to reach wider audiences. To achieve a faster breakthrough in society's attitude towards soil, it is necessary to simultaneously invest in teaching at the basic, vocational and higher education levels and provide information in an attractive format to the general public. The campaign of the Soil of the Year in Estonia since 2014 has proved to be a successful initiative to introduce the diversity of soils to the general public, which has also received more attention in the media. Our goal is to show how we have contributed to the promotion of soil education at all levels of education and popularized the field in Estonia over the past 15 years. We highlight the progress and challenges in developing and implementing new teaching materials and programs. In the modernization of soil education at both university and basic education levels, we have increased interdisciplinary, the share of practical work and involved interactive teaching methods (such as virtual tours).

Applied shorter program fosters a deeper understanding of soil as a dynamic and complex ecosystem, emphasizing its significance in supporting biodiversity, food production and environmental health. Through hands-on activities, interactive experiments, even sportive games and engaging lessons, pupils (also the students) will explore that physical, chemical and biological aspects of soils. The soil programs are designed to cater to various learning styles, ensuring inclusivity and promoting active participation. By incorporation real-world examples and case studies we provide practical insights to the applications of soil science in agriculture, forestry, conservation etc. The soil based study programs (sometimes small learning-bites) emphasizes the importance of responsible soil stewardship, encouraging learner to become environmental advocates and contributing to the well-being of the soil and surrounding environment.

SILVOPASTORAL SYSTEMS AS A STRATEGY FOR SOIL-RELATED ECOSYSTEM SERVICES RESTORATION IN THE COLOMBIAN AMAZON

A.M. SILVA OLAYA, F.A. ORTIZ-MOREA, D.A. MORA-MOTA, A. OLAYA-MONTES, M.P. LLANOS

University of the Amazon, Amazonian Research Center CIMAZ-MACAGUAL, Florencia, COLOMBIA

Soil performs a multitude of ecological functions and underpinning the provision of a wide array of ecosystem services (ES). However, the soil degradation due to land use change can affect the capacity of soil to supply these diverse ES. In the Amazon region, particularly in Colombian portion, the widespread conversion of forest into extensive pastures has led to degradation of soil's physical, chemical, and biological properties. This degradation has, in turn, impaired the ability of livestock systems to deliver essential provisioning services, including food production. To mitigate the negative effects of traditional pasture management practices, alternative systems, such as silvopastoral systems, have been introduced in recent years. Silvopastoral systems combine trees and shrubs with tropical grasses in an integrated approach to agricultural land management. Despite recognized benefits to soil and ecosystem from those integrated production systems, the specific impacts of such management practices on soil's ability to supply ES it is still poorly understood. In this study, we used a comprehensive assessment framework based on primary soil information to evaluate the influence of silvopastoral systems adoption in Colombian Amazon on the ability of soil to provide five soil-related ES: i) Support plant growth, ii) carbon storage, iii) nutrient cycling, iv) erosion control and v) water regulation and aeration. We also studied synergies and trade-offs among these ES. Our findings indicate an enhancement in four ES, particularly plant growth and nutrient cycling, with ES indices rising from 0.45 and 0.75 in pasture to 0.74 and 0.91 in silvopastoral systems, respectively. The overall soil-related ES index increased from 72% in pastures to 83% in silvopastoral systems, highlighting the clear benefits of these systems in restoring soil's ability to supply ecosystems services. A significant interdependence among the ES was observed. Our results underscore the need to re-evaluate and adjust management practices to reduce the impact of livestock systems on soil-related ES in the Colombian Amazon.

#### UNDERSTANDING FOREST SOIL HEALTH

R. KOLKA

USDA Forest Service Northern Research Station, Grand Rapids, USA

Improving soil health is goal for all land managers, either in agriculture or forestry. Much research has been conducted to determine important metrics to assess agricultural soil health but there has been little research on assessing forest soils. Similar to agricultural soil health, maintaining forest soil health during management activities while drive future forest conditions. To test forest soil health metrics and develop a similar approach to the Cornell CASH (Comprehensive Assessment of Soil Health) framework we used CASH across a gradient of forest soils to a chronosequence of soils converted from forest to agriculture. Results indicate that forest soil health is greater than agricultural soil health, independent of years since conversion and that smaller sets of metrics that are not correlated such as those in the CASH framework, are able to predict soil health across the forest to agricultural conversion chronosequence. Those metrics include soil organic matter, soil pH, and wet aggregate stability and a several chemical nutrients with iron being the predominate important micronutrient. The metrics developed in CASH are better able to predict soil health with time since conversion indicating that other non-CASH soil health metrics should be considered when assessing forest soil health.

#### SOIL PROPERTIES AND NUTRIENT LOSSES BY EROSION IN ABANDONED AREAS WITH NATURAL VEGETATION COMPARED TO THOSE OF CROPLANDS

M.C. RAMOS<sup>1</sup>, I. LIZAGA<sup>2</sup>, L. GASPAR<sup>3</sup>, A. CATALÁ<sup>3</sup>, A. NAVAS<sup>3</sup>

<sup>3</sup> Estación Experimental de Aula Dei, EEAD-CSIC, Zaragoza, SPAIN

The abandonment of cropland represents a land use change that has effects on soil quality. There may be some positive effects associated with increased soil cover, but there may also be changes in nutrient content and erosion processes, especially in mountainous environments. This research presents an analysis of the impact of cropland abandonment on soil properties, including texture, organic carbon, nitrogen and phosphorus in abandoned areas covered with natural vegetation compared to those of cropland. The study was carried out in an agroforestry catchment with a Mediterranean climate, located south of the Pyrenees (Aragon, Spain). The effects of erosive rainfall recorded in seven measurement campaigns over two years on the amount and composition of soil particles detached and subsequently exported under both land uses were assessed and compared. After abandonment, soil organic carbon increased significantly, reaching contents almost three times higher than in cropland. This contributed to a decrease in soil erodibility, resulting in less sediment generation after erosive rainfall events, which were on average three times lower in the abandoned areas than in the cropland. Soil nitrogen also increased on abandoned land, reaching values up to about twice as high as on cropland (0.26% versus 0.13%, on average). Phosphorus content, however, was higher on cropland than on abandoned land (416 vs. 217 mg/kg), representing a potential risk to water due to the higher erosion rates recorded on cropland. The results also confirmed the association of phosphorus to smaller particles and the link with SOC on abandoned land, as well as the effect of rainfall intensity on phosphorous mobilisation. Nitrogen losses, however, were mainly driven by the amount of rainfall recorded. This research contributes to identify impacts on agroforestry systems due to the current context of coexistence of conversion of natural areas into cultivated land while in other regions revegetated natural areas are developed from abandoned agricultural areas.

#### SOIL QUALITY AND SOIL CARBON MANAGEMENT INDEX UNDER DIFFERENT LAND USE SYSTEMS AND SOIL TYPES IN THE TYPICAL BLACK SOIL REGION OF CHINA

M ZHANG <sup>1</sup>, J.Q. HAN <sup>1,2</sup>, C LI <sup>1,2</sup>, E.J. YANG <sup>1,2</sup>

<sup>1</sup> College of Soil and Water Conservation Engineering and Science, Northwest A&F University, Yangling, Shaanxi province, CHINA

<sup>2</sup> Institute of Soil and Water Conservation, Chinese Academy of Sciences, Yangling, Shaanxi province, CHINA

Assessing soil quality and soil carbon (C) loss influenced by land use changes facilitates sustainable land use and soil management. Based on principal component analysis (PCA) and soil quality index method (SQI), a minimum data set (MDS) was established to systematically evaluate the soil quality with different duration (0, 10, 20, 30 years) of dryland-to-paddy conversion in two main soil types (meadow and albic soil). This study also investigates soil physicochemical properties, soil aggregates, and C management index (CMI) in three different LUSs (grassland, dryland, and paddy field) under two STs (meadow soil and albic soil) of the Sanjiang Plain in northeast China. The MDS was composed of soil organic carbon (SOC), available phosphorus (AP), nitrate nitrogen (NO<sub>3</sub>-N), available potassium (AK), fine sand (FS), coarse sand (CS), and pH; in meadow soil, the SQI raised significantly in the first 10 years and reached the lowest in the 30 years, and the SOC and AK were the main properties affecting SQI; for albic soil, the SQI was stable within 20 years and then declined significantly in the 30 years, and SOC was the main reason for the change of SQI; soil properties were affected by LUS and ST, especially soil chemical properties; ST had no significant effect on soil aggregates, while LUS had a significant effect on soil aggregates. The heterogeneity of grassland, dryland, and paddy field showed that different LUSs had particular effects on SOC and its active components because LUS had significant effects on C pool index (CPI) and CMI, but ST and its interaction had no significant effects on CPI and CMI. Overall, the results showed that LUS was an important factor affecting CMI in the Sanjiang Plain, rather than ST, and the paddy field CMI was optimal in the Sanjiang Plain. The finding can enable soil quality diagnosis and sustainable development of farmland related to LUS conversion in the typical black soil area in the future.

#### TEMPORAL CHANGE IN MICROBIAL COMMUNITIES AND ACTIVITIES FOLLOWING A CHANGE IN CULTIVATION PRACTISE

B. KULLI <sup>1</sup>, S. HEINIGER <sup>2</sup>, L. MATILE <sup>1</sup>, B. FREY <sup>3</sup>, R. BERGER <sup>1</sup>

<sup>3</sup> Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, SWITZERLAND

In a recent project, we found that hors-sol cultivation in greenhouses influences biological soil properties leading to decreased microbial activity and taxonomic shifts in bacterial communities. As crop rotation areas are protected in most parts of Switzerland, the question arises how quickly a soil restores the activity and microbial composition after cover removal and revegetation. To clarify this question, an area in a tree nursery that was previously covered with permeable plastic sheets and usually serve as a surface for potted plants was investigated. We analysed the soil microbial activities and bacterial composition changes. Freshly uncovered and vegetated plots were compared to control plots that remained covered and to reference plots in a nearby agricultural soil outside the tree nursery. The first three samplings were carried out two months apart after cover removal, followed by two further samplings with intervals of one year.

Microbial biomass, basal respiration and organic carbon content were significantly lower in the experimental and control plots compared to the reference plots. The metabolic quotient, which is an indicator of disturbance in the system, was significantly higher. A slight recovery of the microbial biomass, basal respiration, and metabolic coefficient in the restored areas was observed when comparing with the values of the reference plots outside. In contrast, the bacterial community composition did not converge to those of the reference area after two years (Figure below). We conclude that the new vegetation stimulated the activity and growth of the soil microbiome but did not lead to changes thereof. More detailed investigations of the bacterial composition should show whether, in addition to the coverage, the compaction and the associated restriction of water conductivity, observed at the tree nursery site, is a reason for unchanged bacterial communities and thus is an inhibitor for the recovery of the soil microbiome

Figure: PCA for bacterial community composition for treatments and sampling times.

#### LAND USE CHANGE CONSEQUENCES ON THE QUALITY OF DIFFERENT VOLCANIC SOILS OF CHILE

S.R. VALLE<sup>1</sup>, B. CAURAPAN HENRIQUEZ<sup>1</sup>, R. VERGARA<sup>1</sup>, F. ZUÑIGA<sup>2</sup>, J. CLUNES<sup>1</sup>, O. MARTÍNEZ<sup>3</sup>, J. DÖRNER<sup>1</sup>

<sup>1</sup> Inst. Ing. Agraria y Suelos, Fac. Cs. Agrarias y Alimentarias, CISVo, U. Austral de Chile, Valdivia, CHILE

<sup>2</sup> Inst. Bosque y Sociedad, Fac. Cs. For. y Rec. Naturales, CISVo, U. Austral de Chile, Valdivia, CHILE

<sup>3</sup> Inst. Bioq. y Microbiología, Fac. Ciencias, CISVo, U. Austral de Chile, Valdivia, CHILE

Land use change (LUC) is one of the most frequent disturbances to which the volcanic soils of southern Chile have been subjected. Its consequences do not respond to the same pattern as soils of crystalline mineralogy, given their particular characteristics. Therefore, the objective of this work is to evaluate the changes in the quality of different types of volcanic soils in southern Chile. For this purpose, soils were collected in allophanic, non-allophanic and crystalline volcanic soils between La Araucanía Region (38.95°LS) to Aysén Region (44.03°), in each soil (LAS-Endoaquand, CNC-Hapludand, HUI-Duraquand, VAL-Hapludand, CUD-Hapludult, LO-Andisol, LN-Andisol) under different LU: native forest (NF), crop (C) and grassland (P). Indicators of physical quality: bulk density-Bd, available water pores-AWP, air capacity-AC and conductivity-KI; and, chemical quality: SOC, pH-H<sub>2</sub>O, base sum-SB, Olsen-P, Al saturation and extractable Al, were measured. Some of the main results show that SOC ranged between (1.0 to > 20.0%), Bd varied between less than 0.40 to over 1.05 g cm<sup>-3</sup>, were in almost all cases the lowest Bd value was found under NF. The AC was higher in most cases in NF>P>C, varying between 5.0-25.8%. For the AWP, ranged between (less than 7.0 to over 25%. Base sum varied among soils being higher for C conditions due the agricultural use. The pH followed the same behavior as SB and Al saturation followed the opposite trend. For C uses, chemical indicators as soil pH, bases sum, Al saturation and P availability were improved and exhibits better values than NF, considering soil function of biomass production. In volcanic soils developed under temperate conditions of Chile, can be concluded that soil quality changes differentially for LUC, depending on the type of volcanic soil (allophanic, non-allophanic or crystalline). Thus the intrinsic characteristics of these soils determine that LUS does not always negatively affect soil quality.

#### OCCURRENCE AND HEALTH RISKS OF SOIL POLYCYCLIC AROMATIC HYDROCARBONS UNDER DIFFERENT LAND USE PATTERNS IN THE YANGTZE RIVER DELTA

Y. WANG

Nanjing Normal University, Nanjing, CHINA

Identifying the health risks of soil PAHs may be beneficial for soil pollution. In the present study, the occurrence and health risks of soil PAHs under different land use patterns in the Yangtze River Delta were studied. The toxicity of PAHs was quantitatively evaluated based on the positive matrix factorization-toxic equivalent quantity model. The incremental lifetime cancer risk (ILCR) method was applied to assess the health risks. The results showed that the PAH concentrations varied between 142.26-9278.51 ng g<sup>-1</sup>. High molecular weight PAHs were found to account for more than 85% of the total. Significant variation under different land use types was observed. The mean soil PAH concentration: industrial area > traffic area > commercial area > residential area > park > farmland. The total predicted TEQ and ILCR values of PAHs were in the range of 15.71-867.35 ng g<sup>-1</sup> and 0.13-9.13 × 10<sup>-6</sup>, respectively. The dominant source of soil PAHs was vehicle emissions in the commercial area (89%) and the traffic (85%) area. Coal combustion contributed 43% to soil PAHs in the industrial area. Children experienced a higher cancer risk than adults due to their sensitivity to the carcinogenic effects of PAHs.

<sup>9</sup> Universidad Central de Venezuela, Caracas, VENEZUELA

<sup>10</sup> Instituto de Ciencias. Benemérita Universidad de Puebla, Puebla, MEXICO

SHIMS aims to support public policies and community activities focused on reducing or reversing soil degradation in Mexico. SHIMS is an Evidence Convergence System constituted of three components:

1) An infrastructure of physical, physicochemical, and biochemical data obtained in 196 thousand study sites between 1968 and 2023, and data on factors of change such as deforestation, urban sealing, parcel fragmentation, and management practices reported in the Surveys, Censuses and Records of 2.2 million agricultural parcels.

2) A team of independent experts with a multidisciplinary approach who has debugged the data, calculated, and evaluated the impact of the change factors in the soil compaction, salinization, carbon losses, agricultural drought, and soil erosion through photointerpretation, numerical analysis, and remote sensing at different scaling levels, and

3) A cartographic platform for public feedback on these indicators that includes the participation of non-specialized citizens affected by the change phenomena.

The main challenge of SHIMS is to improve the representativeness, connectivity, and scaling of soil information. Recently, to overcome this, the SHIMS processes have been employing calibration systems and mathematical techniques that can synthesize and preserve the experience of producers and field specialists and that can represent metrics both in a static Euclidean way (e.g., SOC stocks) and dynamically, under multiple position-moment structures such as phase spaces (e.g., SOC losses and gains) through tools based on Bayesian inference and neural networks driven by AI technics.

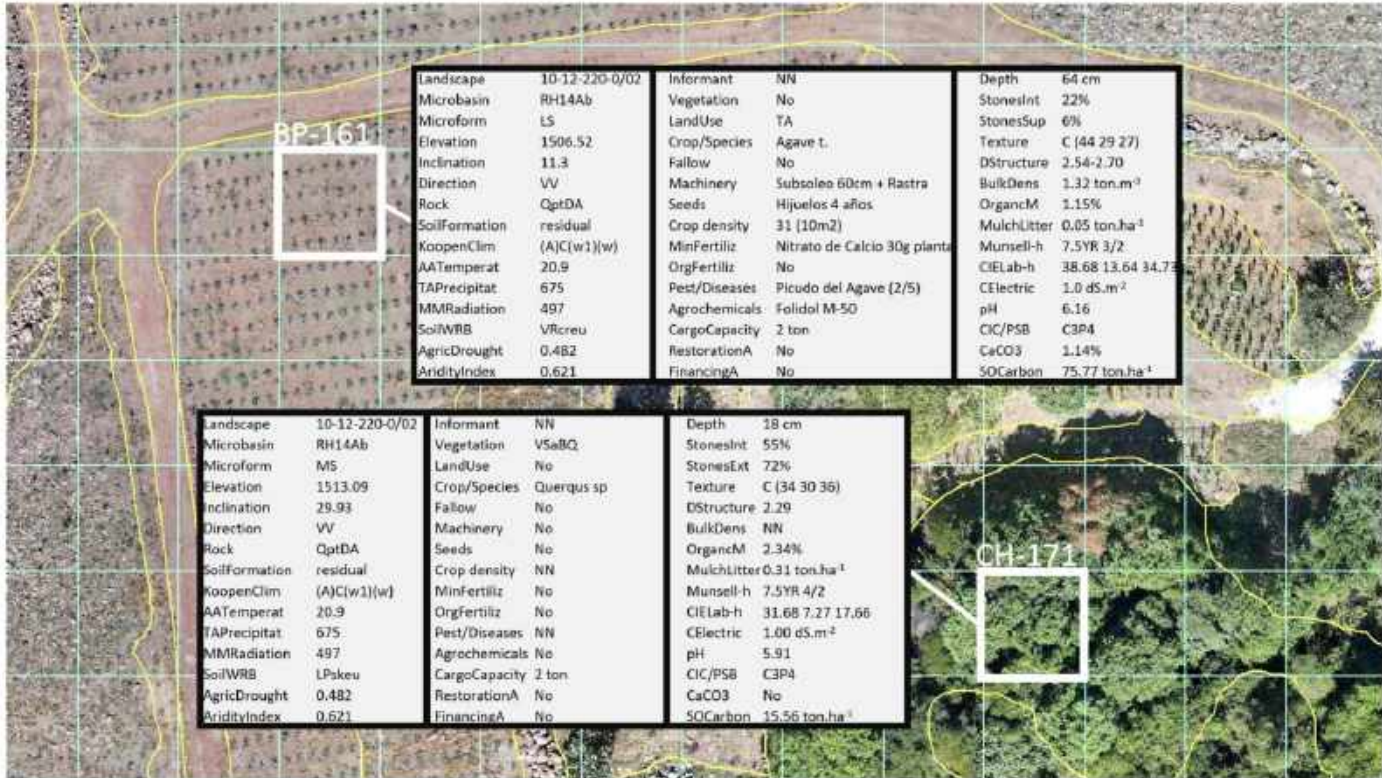

One of the by-products resulting from SHIMS is the set of 28 national scale soil maps included in the "National Atlas of Mexico 2022", a historical document edited by the UNAM-Institute of Geography. The maps show a country deeply disturbed during the last two decades: 5 Mha deforested, 0.4 Mha with recent sealing, the increase to 0.4 Mha of agricultural land with accelerated hyper-salinity or hyper-sodicity (see image), 7.2 Mha with intense anthropogenic erosion and carbon losses 0.03% of national stock each year in Mexico. ### POTENTIAL OF AUTONOMOUS FIELD ROBOTS TO IMPROVE SOIL HEALTH IN DIVERSIFIED CROPPING SYSTEMS: A PROMISING TOOL TO BOOST SUSTAINABLE INTENSIFICATION OF AGRICULTURE

K GRAHMANN

Leibniz-Centre for Agricultural Landscape Research (ZALF) e.V., Müncheberg, GERMANY

The increasing demand for spatial crop diversification, characterized by the presence of different crops within a single field, smaller field sizes and spot management, presents unique challenges for conventional farming. Agricultural diversification, and in particular crop heterogeneity, was found to effectively increase biodiversity and ecosystem services. Diversified cropping systems with new spatial field arrangements, wider crop rotations, and site-specific crop selection require innovative technologies to support management and decision-making. Autonomous field robots offer a promising solution by providing targeted and efficient management measures, tailored to the specific needs of each crop. By leveraging advanced sensing technologies and machine learning, field robots can optimize resource allocation and crop protection, leading to improved crop productivity and farm economy. However, it is yet unknown how the introduction of robots will affect soil conditions over time due to lighter weight, more frequent but slower overdrive, regular mechanical weeding, site-sensible behaviour and high precision compared to large machinery in conventional farming. Although their overall mode of mechanization will most likely not differ from a technical point, differences in workflow, operation procedure and intensity of use may change, as well as the cropping system itself in which field robots are introduced for regular crop interventions.

Therefore, this talk aims to summarize the existing knowledge about the effects of autonomous field robots on specific soil properties, such as compaction, soil structural changes, and aggregate composition for different field robot types and crops and to evaluate their potential for future healthy soil management. A literature review was conducted on studies assessing relevant soil property changes due to agricultural robots and revealed a very limited number of research.

The lack of knowledge on soil chemical, structural and biological changes caused by field robotics underlines the urgent need for comprehensive research in this respect to strengthen the potential of field robots towards sustainable agricultural production.

#### DRIVERS OF SOIL HEALTH IN THE EUROPEAN UNION: A SCOPING REVIEW AND META-ANALYSIS

S. CHOWDHURY <sup>1</sup>, M. VON POST <sup>2</sup>, R. ROCA VALLEJO <sup>3</sup>, K. NAPICH MORA <sup>3</sup>, J. HULTMAN <sup>4</sup>, K. HELMING <sup>1</sup>

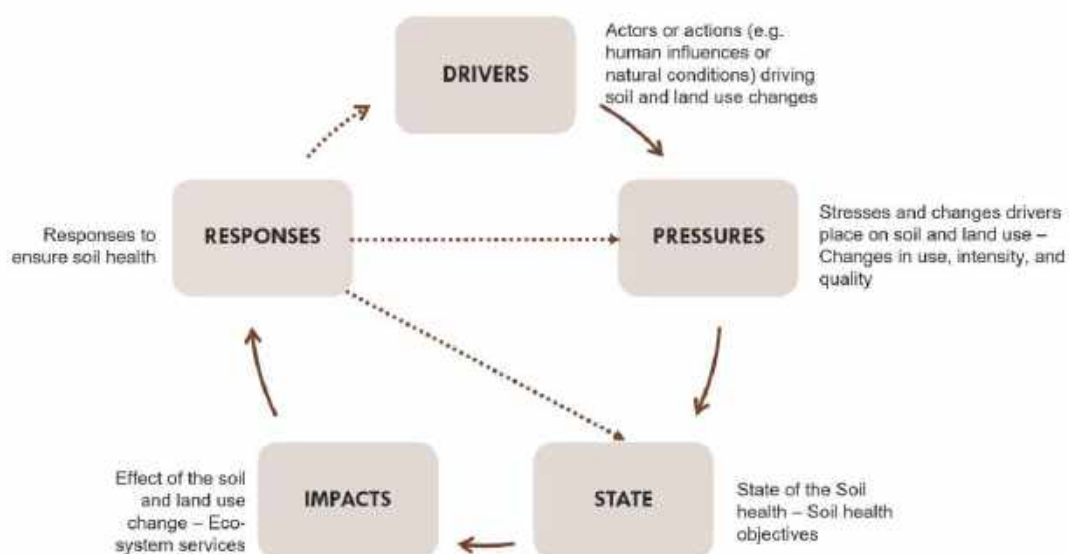

<sup>1</sup> Leibniz Centre for Agricultural Landscape Research (ZALF), Müncheberg, GERMANY

<sup>2</sup> Lund University - Department of Biology, Biodiversity, Lund, SWEDEN

<sup>3</sup> ICLEI European Secretariat, Freiburg, GERMANY

<sup>4</sup> Natural Resources Institute Finland (Luke) - Department of Natural resources, Helsinki, FINLAND

Soils are the basis for all life on land and are crucial for all natural and human processes. However, soil health in EU has reached a critical point: it is estimated that 60-70% of European soils are unhealthy, due to centuries of exploitation. Changes in land-use have a significant impact on soil health and thus, on the quality and quantity of ecosystem services soils can provide. The aim of this ongoing study is to investigate what is driving the changes in soil and land management in the EU in order to identify and understand the emerging opportunities and challenges related to soil health. The DPSIR (drivers, pressures, state, impact, response) framework was adapted to the context of soil and land-use change and used as an analytical framework for connecting drivers of changes in land-use to soil health objectives. A scoping literature review is conducted to identify the drivers which will further feed into the analysis of the links between pressures (changes in soil and land management), and states (soil health objectives) and the respective impacts (ecosystem services). The literature review is divided in four parts based on different land-uses (urban and industrial, agriculture, forest, and nature) and is conducted in accordance to the PRISMA protocol. Around 40000 references have been scanned to filter relevant studies and compile a list of drivers of soil health. The initial results show that climate change is a driver in all land-use types, triggering multiple changes in land use and management and impacting all soil health objectives in all areas of the EU. Urbanisation, changing consumption patterns, and EU policies and legislations have also been identified as drivers with the potential to significantly change land-uses in the EU in the future. This study is carried out as part of the EU Horizon project SOLO. The results of this analysis will feed into the development and establishment of think tanks for each EU soil mission objectives.

#### INTERCROPPING ENHANCES SOIL HEALTH: EVIDENCE FROM LONG-TERM FIELD EXPERIMENT

L LI <sup>1</sup>, X YIN <sup>1</sup>, X LI <sup>1</sup>, C WANG <sup>2</sup>, S YANG <sup>2</sup>

<sup>1</sup> China Agricultural Univeristy, Beijing, CHINA

<sup>2</sup> Gansu Academy of Agricultural Sciences, Lanzhou, CHINA

Intensive agriculture, featured as monoculture with high agricultural chemicals input, has led some problems with soil degradation, biodiversity losses, food production instability etc. Intercropping, growing at least two crops at the same time in the same field, can enhance productivity, and reduce year-to-year variation in productivity under changing climate. The objective of this study will investigate the soil health in decade time scale using a long-term intercropping field experiment.

The long-term field experiment, initiated in 2009, was a split-plot design with three replications, located at Jintan Experimental Station in Jinyuan county, Gansu Province, Northwest China. The main factor is three P application rates including 0, 40 and 80 kg P ha<sup>-1</sup> yr<sup>-1</sup>, and the second factor is nine cropping systems consisting of 5 monocultures (faba bean, soybean, chickpea, oilseed rape and maize) and 4 intercropping systems (maize/faba bean, maize/soybean, maize/chickpea, and maize/oilseed rape intercropping). Physical, chemical and biological properties of soils were examined respectively in 2012 and 2020, soil health index was calculated.

Results showed that at 4th years (2012) after the experiment was established intercropping enhanced the proportion of soil macro-aggregate (> 2 mm diameter) by average 10.1%, and increased soil total N by average 1.0 %, acid phosphatase, urease, nitrate reductase, and sucrose activities by average 6.9% - 105%, whereas maintained soil organic unchanged, compared with the matched monocultures across all four crop combinations. At 12th year (2020) after the experiment was established, intercropping enhanced the weighted mean diameter of soil aggregate by average 23.8 (ranged from 9.46% to 34.1%), soil organic carbon by average 1.61% (ranged from -0.87% to 4.73%), the four soil enzyme activities by ranging from 7.8% to 30.8%, and reduced soil Olsen-P, compared with matched monocultures across four crop combinations. Soil health index, in 2020, in intercropping was significant higher than those in matched monocultures regardless of crop combinations. These results indicated that intercropping enhanced soil health under long-term scale.

#### IMPROVE SOIL AND WATER HEALTH AND PRODUCTIVITY BY CHANGING LAND USE

G. FENG<sup>1</sup>, D.B. REGINELLI<sup>2</sup>

<sup>1</sup> USDA-ARS, Genetics and Sustainable Agricultural Research Unit, Mississippi State, USA

<sup>2</sup> Silver Bayou Consulting, Inc., Starkville, USA

Many agricultural production regions in the world have been experiencing soil health degradation and groundwater resource depletion, which threaten water and food security and soil sustainable productivity if mitigation practices are not developed and implemented. Land, water and soil use changes can build soil and water health and productivity. We investigated soil health as affected by land use, crop rotation, cover crop (CC), soil amendments (biochar, manure, FGD, gypsum, lignite), no-till, and irrigation schedule in the southeast USA. The research identified nine indicators that can capture overall soil health information. Manure improved soil health more than CC under no-till. The combination of manure and gypsum can improve soil health under CC rather than no CC conditions. long-term application of biochar improved soil health in five commercial no-till fields. Soil carbon, N, P, K and pH were significantly increased from uncultivated native vegetation lands to organic farming system. However, the soil health showed a decreasing trend with increasing application years of organic farming, suggesting the need for changes in local organic farming management. Land use dataset showed 80% of the region is cropland. Corn, soybean, and rice consumed approximately 96% of the total amount of groundwater irrigation. irrigation scheduling based on plant water demand could save 47% of groundwater currently used by conventional irrigation. Converting grasslands to forests contributed to reducing groundwater declining. A critical range of soil organic carbon for plant available water content from 14 to 18 g kg<sup>-1</sup> could significantly improve soil water holding capacity. The studies will benefit other regions with similar issues and conditions around the world.

RESPONSE OF SOIL ORGANIC CARBON STOCKS AND SOIL MICROBIAL BIOMASS CARBON TO GRASSLAND CONVERSION: A GLOBAL META-ANALYSIS

J. JIANG, Y. CAI, T. LONG

Nanjing Institute of Environmental Sciences, MEE, Nanjing, CHINA

The conversion of grasslands to other land types, such as cropland and forest, alters the soil carbon cycle and thus affects carbon stocks. However, the potential impacts of grassland conversion to different land use types on soil organic carbon stocks (SOCS) and microbial biomass carbon (MBC) remain uncertain, as does the response to various environmental factors. Here, we performed a meta-analysis to quantitatively assess the effect of grassland conversion on SOCS and MBC based on 548 and 88 individual observations from 85 peer-reviewed articles, respectively. Overall, the conversion of grassland to other land uses significantly reduced SOCS and MBC by an average of 10.11% and 30.63%. Meanwhile, various land use conversion types had notable effects on both SOCS and MBC. In terms of SOCS, the conversion of grassland to forest, cropland and plantation significantly reduced SOCS by 7.69%, 16.47% and 20.55%, respectively, while conversion to managed grassland (artificial grassland, pasture, etc.) and abandoned land had no significant effect on SOCS. Regarding MBC, the conversion of grassland to cropland and abandoned land resulted in a significant reduction of MBC by 47.80% and 38.74%, whereas the conversion to forest, plantation and managed grassland had insignificant impacts on MBC. In addition, the screening of key factors revealed that climatic factors (Mean Annual Temperature (MAT) and Mean Annual Precipitation (MAP)) and soil properties (Soil Total Nitrogen (soil TN) and Soil Carbon to Nitrogen Ratio (soil C/N)) were the factors with the highest degree of influence. Among them, the lower the MAT, the higher the MAP, and the greater the loss of SOCS and MBC after grassland conversion. The smaller the soil C/N (< 10), the relatively stronger the sequestration capacity of soil organic carbon. Our results provide scientific evidence of how grassland conversion affects SOCS and MBC, offering new insights for enhancing the carbon sequestration potential of land.

#### CHANGES IN GRAPE RHIZOSPHERE BACTERIAL COMMUNITY ALONG THE EFFECTS OF SOIL TILLAGE INTENSITY

B. KOVACS<sup>1</sup>, B. BIRO<sup>2</sup>, B. SZOKE<sup>1</sup>, Z. KOTROCZO<sup>3</sup>

<sup>1</sup> Hungarian University of Agriculture and Life Sciences - Department of Viticulture and Enology, Keszthely, HUNGARY

<sup>2</sup> Hungarian Soil Science Society-Department of Soil Biology, Budapest, HUNGARY

<sup>3</sup> Hungarian University of Agriculture and Life Sciences - Department of Viticulture and Enology, Badacsony, HUNGARY

<sup>4</sup> Hungarian University of Agriculture and Life Sciences -Department of Agro-Environmental Studies, Budapest, HUNGARY

The bacterial community of vineyards' rhizosphere has been subjected to a considerable amount of research, but it is still unclear how the applied soil cultivation methods change the structure, composition and level of diversity of their communities. Rhizosphere samples were collected from three neighboring vineyards with the same planting material.

Our objective was to examine the diversity of bacteria in vineyards that differ only in the methods of tillage procedure applied, namely Intensive, Extensive and Abandoned. For that we took samples from two depths (10-30 and 30-50 cm) of the grape rhizosphere in each vineyard and in laboratory immediately prepared the slices of the roots for DNA based analysis of the bacterial communities. The applied methods were first PCR and amplification of 16S rRNA gene, cloning sequencing and phylogenetic analysis. Based on band intensity and position on the results of the DGGE analyses, the diversity of the microbial communities was analyzed by Shannon-Weaver index (H').

Between of the Abandoned and Extensive vineyards at the samples from 10-30 cm the similarity of the community structure was 55% but at the samples from 30-50 cm was more than 80%, while the difference between of the Intensive and to other two was also more than 80%.

Based on our results we can conclude that intensive physical cultivation effect strongly the structure of the bacterial community and its diversity. The evaluation of farming practices should also take this parameter into account while looking for the sustainable alternatives for the future.

#### FRAGILITY INDICES FOR SOILS OF CHILEAN PATAGONIA

F. ZÚÑIGA UGALDE<sup>1</sup>, S. VALLE<sup>2,3</sup>, R. VERGARA<sup>2,3</sup>, J. CLUNES<sup>2,3</sup>, D. PINOCHET<sup>2,3</sup>

<sup>1</sup> Instituto de Bosques y Sociedad, Valdivia, CHILE

<sup>2</sup> Instituto de Ingeniería Agraria y Suelos, Valdivia, CHILE

<sup>3</sup> Centro de Investigación en Suelos Volcánicos (CISVo), Valdivia, CHILE

Soils are a non-renewable natural resource. Their maintenance depends on their natural properties (e.g. type of clay) and their management (e.g. fertilisation). The construction of soil indexes are useful tools to assess the interaction of these properties and to evaluate the state of the soil ecosystem functions. We used soil quality concepts to construct soil fragility index (SFI) for five land uses in Chilean Patagonia.

174 soil samples were collected from 43°41'8" S 72°19'60" W to 46°53'30" S 72°47'16" W to construct SFI for native forest (NF), grassland (G), exotic plantations (EP), cropland (C) and wetlands (W). Soil organic carbon (SOC), bulk density (dB), exchangeable aluminium (Al) and soil pH in NaF, CaCl<sub>2</sub>, KCl were determined in laboratory. Principal component analysis (PCA) was used to identify the main variables and the weight of these variables in the PCA. Standardised scoring functions were used to transform soil properties into values between 0 and 1 and construct the indices using a modification of the methods proposed by Andrews and Carroll (2001) (SFI-A) and Kuzyakov et al. (2020) (SFI-B).

SOC, dB and Al saturation were the main variables explaining PC1 with weight factor values of 0.335, 0.305 and 0.682 respectively. The SFI-A ranged from -0.71 to -1.10 while the SFI-B ranged from -2.02 to -5.29. Regardless the method used, soil fragility was W > NF > C > EP > G. The high SFI values in W and NF are strongly influenced by SOC and dB together, these properties, accounting for 66% of SFI. C, EP and G are influenced by Al saturation, accounting for 90, 80 and 50% respectively of the indices in these land uses. SFI-B reflected better the differences between land uses compared to SFI-A.

#### LAND USE IMPACT ON SOIL RESPIRATION AND SOIL MICROBIAL ACTIVITY

S. KAPTANOGLU, U. SAHIN, F. ATALAR, A. SARIMEHMETOGLU

RESEARCH INSTITUTION FOR FOREST SOIL AND ECOLOGY, ESKISEHIR, TURKEY

Changes in soil characteristics resulting from land use alterations have been a subject of increasing interest in environmental research. This phenomenon is often associated with the adaptation of pristine areas to various land uses, causing significant impacts on ecosystems. Notably, soil carbon stores and atmospheric CO<sub>2</sub> emissions are directly influenced by these adaptations in land usage practices and management.

In contrast to existing scientific literature our study contributes to the understanding of carbon pool mechanisms by focusing on a terrestrial region of the Mediterranean with contiguous land uses: poor, fair, and good pasture lands, two agricultural areas fallow, larch pine and cedar afforestation areas and finally degraded oak and juniper forests. Measurements of soil and CO<sub>2</sub> flux were conducted every month for a year in the fields and soil moisture and temperature values were recorded.

The study found that native oak and juniper forests, as well as larch and cedar plantations, exhibited higher levels of soil respiration, CO<sub>2</sub> flux, and microbial biomass. Following the trend observed especially in forests, a noticeable decrease in soil respiration values was observed from pastures to fallow agricultural fields. Soil respiration values are 5.5 t ha<sup>-1</sup> year<sup>-1</sup> in oak forests, 5.4 t ha<sup>-1</sup> year<sup>-1</sup> in larch plantations, 5.3 t ha<sup>-1</sup> year<sup>-1</sup> in cedar areas, and 4.8 t ha<sup>-1</sup> year<sup>-1</sup> in cedar forests. 4.6 t ha<sup>-1</sup> year<sup>-1</sup> in juniper forests, and pasture areas, 4.1 t ha<sup>-1</sup> year<sup>-1</sup> are in fallow agricultural areas, respectively. There was also a positive correlation between CO<sub>2</sub> flux and microbial biomass values and both soil respiration values and soil moisture levels.

It is thought that it would be beneficial to spread the observations made within the scope of the project to different land uses (agricultural areas where different crops are grown, orchards, mining areas, etc.) and for a longer period.

#### THE IMPACT OF CHRONIC DISTURBANCE BY GRAZING ON SOIL PROCESSES IN SEASONALLY DRY TROPICAL FORESTS

D. PINCHEVSKY<sup>1,2,3</sup>, C.I. ESPINOSA<sup>4</sup>, A.K. JARA-GUERRERO<sup>4</sup>, J. GRÜNZWEIG<sup>3</sup>, B. GONZÁLEZ-SÁNCHEZ<sup>1</sup>, A. ESCUDERO<sup>1</sup>, L. MERINO-MARTÍN<sup>1</sup>, A. REY<sup>2</sup>

<sup>4</sup> Universidad Técnica Particular de Loja, Ecuador, Loja, ECUADOR

Seasonally Dry Tropical Forests (SDTF), constituting over half of the forest cover in tropical regions, have undergone significant anthropogenic deforestation in recent centuries. The impact of human activities on soil microbial communities in these forests remains poorly understood despite their crucial role in providing vital ecosystem services, such as organic carbon storage, nitrogen fixation, and nutrient cycling. One of the main human disturbances in these SDTFs is livestock grazing which has been barely studied. To address this knowledge gap, we conducted a field study in a SDTF in the province of Zapotillo, southern Ecuador. We identified five stages along a chronic disturbance gradient (as a result of goat grazing) and selected five replicate plots for each stage. In each forest plot, we collected composite soil samples and measured microbial respiration and its response to temperature, functional diversity by community-level physiological profiling (CLPP), total carbon and nitrogen, and nutrient concentrations. Our findings unveiled that the two most severely disturbed stages exhibited lower soil carbon and nitrogen concentrations, along with reduced soil carbon mineralization and lower temperature sensitivity. Additionally, phosphorus levels were lower in the more intensely disturbed areas compared to the less disturbed ones. These results suggest that low intensity goat grazing may be sustainable for microbial-related soil processes in these dry tropical forests. However, beyond a certain threshold, goat grazing can disrupt natural processes, leading to lowering of soil fertility and reduced carbon retention. This study emphasizes the potential consequences of goat grazing on ecosystem dynamics, the forest carbon cycle and ultimately, forest sustainability. These findings highlight the importance of sustainable land management practices to preserve the delicate balance of these unique ecosystems.

#### THE ROLE OF SITE PROPERTIES AND MANAGEMENT HISTORY FOR SOIL HEALTH

M.K. KLEBER

Oregon State University, Corvallis, UNITED STATES MINOR OUTLYING ISLANDS

Despite the fact that our study involved only 40 potato fields and must therefore be considered of limited size, we succeeded in identifying a number of soil conditions and management practices with the potential to affect soil health in potato fields

- a) Our data suggest that soils in the order of aridisol have particularly weak defenses against the disease.
- b) Mollisols seem to be better in suppressing the disease than aridisols, entisols and inceptisols.
- c) The potato variety showed little correlation with Verticillium disease status. This result was unexpected since there are distinct differences in the susceptibility to disease among potato varieties.
- d) Within the 5-year time frame of our study, it did not matter for disease suppressiveness how much time had elapsed since the last potato crop. With sclerotia being able to survive in the soil upwards of 10 years, this result was probably to be expected.
- e) Soil moisture above a certain threshold seems to be a major factor in disease susceptibility. However, it was not the amount of water during potato years but the overall amount of water supplied to the field that was correlated with disease incidence. This means that irrigation practices between potato years may be of greater importance for disease susceptibility than the irrigation regime chosen while the crop grows!
- f) The fact that diseased fields tend to have a history of significantly more frequent applications of agrochemicals seems to suggest that what is intended to be preventive care to control weeds, pests, and diseases may actually manifest itself as a serious stress factor for soil microorganisms.

#### AN OVERVIEW OF THE ACIDITY OF AGRICULTURAL SOILS IN SLOVENIA

E. ZAGORAC, M. SCUKA, B. VRSCAJ

Agriculture Institute of Slovenia, Department of Agricultural Ecology and Natural Resources (DAENR), Ljubljana, SLOVENIA

Soil is an essential resource for the successful and sustainable production of high-quality food for the world's growing population. Climate change and a growing population expose soils to many threats and degradation processes, including erosion, salinisation and compaction, soil organic matter reduction, flooding, land development and soil pollution. Pressure on agricultural soils and food security are pushing for sustainable soil management. By definition, agriculture changes the acidity of the soil. This fact is unacceptable to some who call for nature-orientated agriculture, even though soil quality could be increased, not decreased, by liming. Farmers and experts recognise that maintaining topsoil acidity is essential for soil fertility. The aim of the study was to find out what is the acidity of the main types of agricultural land uses (arable land, orchards and vineyards) in Slovenia and to produce evidence based on measurements and maps reflecting the impact of agriculture on soil acidity; estimate to what extent the acidity of agricultural soils differs from the natural acidity of the same soil types, whether the acidity is higher/lower and if so, by how much. The old data on the natural acidity of different soil groups were merged with the soil data (acidity measurements) from 2004 to the present to create a map showing effects of agricultural use on soil acidity. The main output of this study is a temporal and geo-referenced database of agricultural and natural soil acidity in Slovenia, statistics of archived soil acidity data for agricultural land and the production of a map of agricultural soil acidity in Slovenia. The geo-referenced data and maps on soil acidity will help guide agricultural practises towards sustainable soil management, liming and fertilisation in order to achieve the optimal acidity of agricultural soils.

<sup>2</sup> AgResearch, Hamilton, NEW ZEALAND

Soil health places emphasis on the living component of the soil, and its contribution to soil processes and functions underpinning the delivery of ecosystem services. Various measures can be used to assess the soil biological community and its activity. However, few measures have targets for optimal populations or the knowledge to manage these, limiting the potential biological indicators available.

We investigate how additional tests of soil biology can be used to provide a more complete picture of soil condition, focusing on the impacts of regenerative management on soil health. A series of trials have been established on pastoral farms across different regions in New Zealand implementing regenerative practices (e.g. increasing pasture diversity and reducing fertiliser inputs). Biological measures are assessed across seasons in conjunction with soil chemical and physical properties. Biological measures include estimates of microbial biomass through commercially available tests (e.g. hot water extractable carbon) as well as field assessment of earthworms and pasture insect pest populations. These measures have target ranges specific to New Zealand. Further measures include nematode community analysis, microbial respiration, soil microbiome and relevant microbial functional genes, and soil disease pressure assays.

Indicators of soil biology (where target ranges available) were often at target in long-term pastures, but not necessarily in more recently converted pastures. Initial data shows that one year after establishing management treatments, differences in the soil biology, as well as soil chemical and physical properties remain limited. Some measures of soil biology, such as earthworms were variable through time and across seasons, while other measures, including hot water extractable carbon remained relatively stable. Soil type and previous land use influenced the soil biological community. We investigate factors driving changes in biological measures, with monitoring set to continue for several years. Only by assessing soil biology across a diverse range of sites using consistent methods, will our understanding improve and allow us to increase biological indicators available for routine evaluation of soil health.

<sup>4</sup> University of Parma - Department of Chemistry, Life Sciences and Environmental Sustainability, Parma, ITALY

Soil arthropods play a critical role in sustaining soil health, moreover they can be used to detect soil alterations. The Mefite Geological Site (Campania, Italy) is a non-volcanic highly degassing site hosting a sulphurous lake, which exhalations affect vegetation in the vast 3km radius. The aim of this study was to evaluate the soil ecotoxicity of the site, and characterise soil arthropod community, underlining its bioindicator role and the taxa that can cope with this environment. Soil cores were sampled at 3 distances from the lake: A) 30m, B) 80m, C) 120m. On those soils were made: soil organic matter (SOM) and pH analyses, ecotoxicity tests on *Folsomia candida* (survival, reproduction), soil arthropods identification (order level, Collembola families, Protura species). Statistical analyses evaluated the impact of sulphurous emissions on soil chemistry and ecotoxicity, and on arthropods parameters (soil arthropods community structure, taxa associations; Shannon and Simpson biodiversity; soil biological quality index – QBS-ar). Results showed no differences in SOM, unlike pH, which were A(3.34±0.15),B(5.18±0.56),C(7.10±0.32). The highest ecotoxic effect on *F. candida* was observed in A. Community composition, as well as QBS-ar, differed in A and B compared to C, and the poorest soil biodiversity was found in A. No orders were associated with A, while Acarina and Coleoptera were linked to B and C, and Tetramerocerata was associated to C. Collembola family composition did not change from one distance to another, however Hypogastruridae resulted clearly associated with A. Protura confirmed to be a sensitive group, absent in A. Given the lack of information on their presence in Campania (3 species registered so far), this study updated the available data providing the first record of 4 species. Arthropod community biodiversity and composition resulted effective soil bioindicators in extreme acidic conditions, reflecting soil ecotoxicity. QBS-ar index showed to be a sensitive tool in sulphureous environments; however, Collembola showed responses at family level, with Hypogastruridae being tolerant to the highest toxic environment investigated.

#### GLOBAL META-ANALYSIS OF SOIL FAUNA RESPONSES TO LAND USE INTENSIFICATION IN AGROECOSYSTEMS: A FOCUS ON EARTHWORMS

B. BETANCUR CORREDOR <sup>1</sup>, A. ZAITSEV <sup>2</sup>, D. RUSSELL <sup>2</sup>

<sup>1</sup> University of Bonn, Center for Development Research, Ecology and Natural Resources Management, Bonn, GERMANY

<sup>2</sup> Senckenberg Museum of Natural History, Goerlitz, GERMANY

The shift from extensive to intensively managed agroecosystems, leading to increased land use intensity, is often regarded as a major factor behind the global decline in biodiversity, particularly impacting soil biodiversity. Understanding the responses of soil biodiversity to diverse land use practices is crucial for effective land management in the context of future changes. Despite substantial evidence, uncertainties persist in predicting the consistent responses of different taxonomic groups to land use intensification.

We conducted a meta-analysis to evaluate the impacts of diverse land use intensification on soil organisms in global agroecosystems. Our study involved compiling a dataset with 3190 pairwise observations from 192 publications, comparing intensified land use to undisturbed ecosystems across 59 countries. Furthermore, we examined the influence of abiotic factors, including soil properties and climatic parameters, on these effects.

Our observations revealed a significant decrease in both the abundance (-34%) and species richness (-16%) of springtails. Conversely, earthworms exhibited a positive trend in abundance (+217%) but a reduction in species richness (-12%). Enchytraeids showed a negative impact on abundance (-32%) without affecting species richness. Mites demonstrated a positive increase in abundance (+129%) but with a notable reduction in species richness (-50%). Nematodes experienced a negative impact on abundance (-7%) without any effect on species richness.

In our assessment of earthworm responses, the impact varied based on specific intensification methods. Positive effects on earthworm abundance were observed in agroforestry (+60%), cover crops, low input cropping (+113%), managed grasslands (+52%), vegetable gardens (+52%), and pastures (+218%). Conversely, negative effects were noted in arable cropland (-24%), orchards (-35%), specialty crops (-61%), crop-livestock integration (-13%), and managed forests (-95%). Higher intensification effects were noted in areas with greater mean annual precipitation, higher soil pH, finer soil textures (clayey, loamy, and silty), and increased organic matter content.

Our results show the complex interaction between land-use intensification and soil fauna, offering insights into sustainable land management practices tailored to diverse ecological contexts.

<sup>4</sup> Univ. Lyon, INSA Lyon, UCBL - MATEIS, CNRS UMR5510, 69621 Villeurbanne, FRANCE

Enchytraeids are small, unpigmented Annelida Oligochaeta belonging to soil mesofauna (diameter between 100  $\mu\text{m}$  and 2 mm, length 6-50 mm). They are anatomically and taxonomically close to earthworms but much smaller. Enchytraeids are abundant in various ecosystems, and they have a key role in organic matter dynamics. However, their influence on soil porosity through bioturbation activity is poorly understood, and the pore network created by these organisms has never been characterized.

Our study aimed to characterize the pore network created by two species of enchytraeids of different size (*Enchytraeus albidus* - length 30 mm, body diameter 0,6-1mm - and *Enchytraeus crypticus* - length 10 mm, body diameter 0,18-0,30 mm) in two different soils using images obtained through X-ray microtomography with a voxel size of 20  $\mu\text{m}$ . Soil columns were scanned before and after enchytraeid activity (at 30 days). 20 grams of a loamy soil or a silty clay loam soil (sieved at 2 mm) were placed in columns of 3.3 cm diameter and 4 cm height. The 2.5 cm of soil was compacted at two different densities (0.8 and 1 g.cm<sup>-3</sup>), and enchytraeids were introduced into the columns for one month. Control columns without enchytraeids were used to assess the effect of transport to the tomograph on porosity modification. Image processing was automated using Fiji and Avizo macros.

The total porosity was not influenced by enchytraeid activity, but the porosity profile over the 2.5 cm of soil was significantly modified, along with the distribution of pore sizes. In these experimental conditions, enchytraeids simplified the pore space by completely reorganizing the environment and creating bioporosity, so altering pore space connectivity, reducing isolated objects and ramifications. The majority of the pore diameters of the space worked by the worms correspond to the diameter of the animal's body. This could significantly impact water flow and particle transport in soils.

#### NEMATODE-MICROBE INTERACTIONS AND THEIR EFFECT ON PLANT HEALTH

T. LIU

Nanjing Agricultural University, Nanjing, CHINA

Nematodes, the most abundant and functionally diverse soil animals, establish intricate relationships with microbes and plants. While commonly recognized for their roles as ecological indicators in response to environmental disturbances and nutrient cycling, less attention has been given to understanding their influence on the microbial community and subsequent impact on plant health. In a series of experiments focusing on soil free-living nematodes, we investigated their interactions with pathogenic bacteria and resident microbes, exploring their collective effects on plant health. Contrary to the assumption that nematodes directly suppress plant pathogenic bacteria through consumption, our findings revealed that the plant pathogenic bacteria *Ralstonia solanacearum* not only cause damage to their host plants but also exhibit toxicity towards non-host soil animals. Instead, nematode predation contributed to an increase in Bacillaene production by antagonistic bacteria, enhancing the antagonists' ability to suppress plant pathogens. Furthermore, the presence of nematodes fostered diversity and co-existence within the resident microbial community, steering the resident bacterial community towards suppressing plant pathogens and promoting plant growth. Our study provides an initial insight into the intricate dynamics of nematode-microbe interactions and their profound implications for plant health.

Soil fertility is crucial for sustainable agriculture and the health of terrestrial ecosystems. Earthworms and bacteria play key roles in creating fertile soils due to their role on organic matter (OM) dynamics and soil structure. This work focuses on the interaction between earthworms and microbial communities in the soil. Understanding these relationships is essential for deepening knowledge about earthworms and developing soil management strategies to enhance fertility.

Experiments were conducted at INRAE Avignon under laboratory and field conditions to examine the contribution of various earthworm species and different types of OM on microbial activity. The analytical tool used was the Fertimetro, patented (WO2012140523A1) by the University of Padova, which quantifies microbial activity and plant nutrients deficiency by measuring the degradation of cotton and silk threads in plain or pre-treated versions with nitrogen, or phosphorus and potassium, which are buried for seven days into the soil.

Through their use, we aimed at verifying whether different species of earthworms and OM inputs could confer differences in thread degradation, and to possibly speculate on how this could be interpreted in judging soil fertility as well as the efficiency of its ecosystem services.

The results highlighted that in laboratory conditions, the presence of OM and, in some cases, earthworms can vary the fiber-degrading activity of soil microbes. Furthermore, some preferences of the different ecological categories for some OM conditions could be observed. In the field, higher microbial activity was measured over time in both inoculated and control conditions. Variations in microbial activity are hypothesized to be due to earthworm presence in particular conditions.

The study showed the effectiveness and the potential of Fertimetro in soil analysis providing valuable insights. Fertimetro can be a valid analytical tool, if based on the study context, for studying earthworms and their interaction with soil and organic matter components, and it can be used to further understand interactions among soil organisms.

#### THREE-YEAR DYNAMIC OF COLLEMBOLA TAXONOMIC AND FUNCTIONAL COMPOSITION IN A POST-FIRE MEDITERRANEAN FOREST

L. SANTORUFO, M. ZIZOLFI, V. MEMOLI, G. SANTINI, G. MAISTO

University of Naples Federico II, Naples, ITALY

Frequent and intense fires in the Mediterranean basin cause significant damage to vegetation, litter, and the top humus horizon. The resulting heat, toxic smoke, and microhabitat destruction lead to changes in the abundance and community composition of soil microarthropods. Recovery time varies and depends on fauna groups, pre-existing vegetation, and soil properties. Collembola, being crucial for several environmental processes and sensitive to disturbances, represents good indicators of environmental changes. Their rapid colonization and reproduction rates make them pioneering organisms in the swift recolonization of disturbed soil.

This research addresses the variability in soil fauna reaction time to fire, which remains insufficiently documented. The study aims to fill this gap by comparing post-fire Collembola assemblages in soils covered by trees and shrubs. Surface soil were collected in spring 2021, 2022, and 2023 (3, 4, and 5 years after the fire) from 24 sites within the Vesuvius National Park (Southern Italy), with each season comprising 12 unburnt (NB) and 12 burnt (B) sites, divided further into 6 covered by trees (T) and 6 by shrubs (S). Collembola were extracted, identified at species level, and analyzed for taxonomical indices (density, species richness, diversity, and evenness) and functional traits (body length, furcula presence, eye presence, pigmentation, and reproduction type).

Three years post-fire, Collembola species composition significantly differed between NB and B areas covered by T and S. This difference persisted after 4 and 5 years, with a more pronounced effect under S soils. Three years post-fire, the highest taxonomical indices were observed in NB-T soils, and after 4 and 5 years, the lower indices persist only under B-S soils. Collembola with pigmentation, furcula, eye and sexual reproduction, linked to the surface environments and indicators of stressed conditions, decreased in both B-S and B-T soils and increased in both NB-S and NB-T soils.

The Collembola community's taxonomic and functional structure was significantly impacted by fire, and it has not fully recovered even after 5 years.

### 4. Soil health in achieving the Sustainable Development Goals 4.15 133566 - Soil fauna as a tool to improve soil health assessment

#### APPLICATION OF THE ARTHROPOD-BASED SOIL BIOLOGICAL QUALITY INDEX (QBS-AR) IN THE CONERO REGIONAL PARK: A COMPARISON BETWEEN THREE ORGANIC FARMING SYSTEMS

M COLETTA, M MONTICELLI, A D'ALESSANDRO, C GENTILI, N WARIS, A LA TERZA

School of Biosciences and Veterinary Medicine, University of Camerino, Camerino, ITALY

Soil microarthropods are recognized as sensitive indicators of the impact of agricultural practices on soil functions. The arthropod-based Soil Biological Quality Index (QBS-ar) is a reliable method to assess soil health, avoiding the difficulties of taxonomic identification to species level.

The EU Biodiversity Strategy 2030 highlighted the significance of organic farming and land protection in halting biodiversity loss. On this point, the study aimed to evaluate the soil health in organic farms within a protected area, using the QBS-ar over a two-year period. The final objective to identify the most sustainable farming system and the best 'good agricultural practices' to preserve soil microarthropods and, more generally, to promote the conservation of soil biodiversity in different agroecosystem types.

Four arable lands, four olive groves, and four vineyards located within the Conero Park (Italy) were studied. The QBS-ar index, number of biological forms, density (ind/m<sup>3</sup>), total abundance, Acari/Collembola ratio, and percentage of Oribatid mites out of total mites were determined. Ordination analysis was used to analyse the soil microarthropod community composition across farming systems.

The results indicate that organic farming combined with land protection has a positive impact on soil health. Most farms demonstrated excellent soil quality, with the highest levels found in arable land. These findings support the "Intermediate Disturbance Hypothesis" (IDH), which suggests that slightly disturbed habitats exhibit higher organism diversity than stable ones. The community structure of microarthropods in arable land differed from that in the more stable arboreal crops. Olive groves had a higher abundance and diversity of microarthropods compared to vineyards, which exhibited lower levels.

This study provides knowledge towards an informed use of microarthropods as bioindicators of soil health. It emphasizes the importance of monitoring biological soil health in protected areas and establishing thresholds for the prevalent farming systems, characterised by different agronomic practices. This is crucial for promoting the use of the QBS-ar index in national/international soil health monitoring.

**SOILGUARD – EFFECTS OF LAND USE AND AGRICULTURAL MANAGEMENT ALONG SOIL DEGRADATION GRADIENTS ON NEMATODES, ACARI AND COLLEMBOLA IN EUROPEAN SITES.**

G. BONGIORNO, R. DE GOEDE

Wageningen University & Research, Soil Biology group, Wageningen, THE NETHERLANDS

Soil health is defined as the capacity of a soil to function within ecosystem and land-use boundaries. Soil biota can sustain a wide range of functions and as such are intrinsically connected to soil health. Land use, soil management and land degradation can affect soil biodiversity and ultimately soil health. Soil fauna is an integral part of soil biodiversity connected at various levels of the food web with other important soil organisms such as bacteria and fungi. Nematodes are ubiquitous organisms that are sensitive to disturbances and can be divided into functional groups based on feeding preferences and life-history strategies. Mites and collembola are two groups of microarthropods that are sensitive to land use change and soil management. These different groups of organisms can be used as indicators of soil biodiversity and health. The objective of this study is to investigate the status of nematode, acari and collembola abundance and diversity upon various land uses, agricultural management, and land degradation levels. The final aim is to connect their abundance and diversity to soil multifunctionality and soil health. Nematodes, acari and collembola community characteristics have been assessed in seven European NUTS regions with different land use (forest, grassland and arable land), management (clearcutting vs continuous cover, grass monoculture vs grass-clover mix, organic vs conventional agriculture), pedo-climatic (texture, climate) characteristics, and land degradation levels (organic matter levels). Nematode, acari and collembola abundance and taxonomic diversity are currently being analysed with traditional morphological methods and the results will be presented during the congress.

The use of bacterial and fungal rhizospheral inocula and their consortia is important for sustainable crop systems when their use allows a reduction of chemical fertilizer inputs and plant protection products, and/or enhance soil biodiversity supporting soil health. Therefore, the identification of suitable ecological indices to assess soil health is crucial for monitoring the effects of those inocula on resident soil communities. In this work we evaluated two inocula i) different endophytic arbuscular mycorrhizal fungi (AMF, n=14) and ii) the AMF with the addition of bio-effectors (i.e., products showing biostimulating effects, AMF\_Bf, n=12) in 16 sites across Europe. Three-year AMF effects on soil-dwelling microarthropod communities were compared to untreated control plots (UTC, n=16) on tomato, strawberry, and apple cropping systems, managed with integrated and organic methods. The microarthropod community was classified in biological forms (BFs) by their functional adaptation to soil life. In total, 4955 animals in 33 different BFs were extracted and identified from 129 soil samples. Seven biodiversity indices based on BFs were compared among the treatments. Results evidenced that the most effective biodiversity indices for the microarthropod community were those based on BF presence (QBS-ar and QBS-ar\_BF) compared to those based on BF abundances (e.g. Acari/Collembola abundance, Shannon, QBS-ab). Overall, AMF treatments increased the arthropod diversity compared to UTC (by 57% cases and 71% cases for QBS-ar and QBS-ar\_BF, respectively). Unexpectedly, the increase rate was less frequent when the bioeffector was added (QBS-ar: 42%; QBS-ar BF: 42%). Indeed, the treatments were more effective under integrated compared to organic management. In conclusion, the novel QBS-ar\_BF index was useful in discriminating among treatments and management systems. In addition, results suggest that organically managed soils, which have a more complex and stable community, may benefit less from AMF treatment. Nevertheless, the inoculation with AMF fungi was beneficial for microarthropod diversity in most cases and encourages new perspectives to enhance soil health.

Farming practices can affect soil health, and soil fauna serves as an effective indicator of these impacts, with different taxa experiencing greater or lesser effects depending on the specific nature of the impact. A comprehensive assessment should therefore consider several organism groups. The evaluation of the effect of farming practices on soil fauna is commonly carried out using several types of indices: (i) abundance indices, indicating the quantity of animals; (ii) taxonomical indices, evaluating taxa diversity; and (iii) functional indices, measuring the roles of taxa in ecosystems. Still, there is no clear evidence on which of these indices is more suitable for the detection of changes in the soil status.

The impacts of farming practices on soil fauna abundance and diversity were evaluated in nine European Long Term Agricultural Experiments (LTEs) across a gradient of pedoclimatic conditions, employing different tillage systems and fertilization practices. In autumn 2022, these LTEs were sampled to assess soil health using also fauna diversity indices, focusing on nematodes, microarthropods, and earthworms to represent micro-, meso-, and macrofauna biodiversity, respectively.

This work will compare the three categories of indices mentioned. The aim is to determine which type of indices are most sensitive in detecting differences in soil fauna communities when organic or mineral fertilization practices and standard, reduced or no tillage management are applied. The development and application of appropriate ecological indices not only will facilitate a more accurate and comprehensive evaluation of soil fauna communities, but it will even contribute to the formulation of targeted conservation and management strategies aimed at promoting long-term soil sustainability.

<sup>1</sup> ISPRA CN\_LAB/BIO Soil & Land Ecology Laboratory, Rome, ITALY

<sup>2</sup> ISPRA, Rome, ITALY

Conventional and organic hazelnut orchards were examined in a first two-year project period (2015-16) and in a second two-year period (2018-2019) in Central Italy. In the former, organic hazelnut farms not located in protected areas showed problems due to the choice of experimental fields to be compared. Therefore, 2015-16 results resulted influenced by the surrounding environment and other management characteristics. During this period, however, a rigorous set of covariates useful for the selection of the study areas was defined. This helped an accurate selection of the comparable crops in the second two-year period. In 2018-2019, the new selected study areas allowed to correctly compare the fields of each organic/conventional pair for all environmental variables considered. This led to statistically significant results comparing the two different types of agronomic management. Pesticide application in the conventionally integrated managed orchards produced substantial effects on soil microarthropod community structure, affected both in soil fauna groups richness and in the specimens' abundance. The results of this monitoring campaign show how effective and efficient can be soil microarthropods as biological indicators of pesticide impact on biodiversity. A series of comparisons illustrate the relative differences and proportions, highlighting the need to protect this fundamental key group and to use it into the monitoring activities, remarking the need for a severe pesticide regulation.

#### EARTHWORM POPULATION IN THE EARLY TRANSITION PERIOD TO ALTERNATIVE TILLAGE SYSTEMS

I. BERTONCELJ, A. ROVANSEK, R. LESKOVSEK

Agricultural Institute of Slovenia, Department of Agricultural Ecology and Natural Resources, Ljubljana, SLOVENIA

In temperate climate zones earthworms are important soil engineers affecting soil structural stability, porosity and nutrient cycling thus influencing agricultural production. The aim of our study was to examine the earthworm population in the early transition period to alternative tillage systems in arable fields in Slovenia by comparing conventional, conservation and no-till systems.

Sampling was carried out in three consecutive years (2021, 2022, 2023) of which 2022 was extremely dry and 2023 extremely wet with local flooding. Field experiment was established at the Infrastructure Center Jablje in central Slovenia in 2018, where a total of 2.8 ha with the same crop rotation have been managed under three tillage systems. In beginning of October each year, we sampled five 30x30 cm areas in each tillage system using a combined field collection method: hand searching of topsoil (0-20 cm) and application of allyl isothiocyanate (AITC) solution at the depth below 20 cm.

Overall, the highest number of earthworms was detected in conservation and no-till systems with conventional tillage supporting fewer individuals. Juveniles were mostly concentrated in the topsoil layer (0-20 cm) but adults were similarly distributed at both examined soil depths. Severe drought in the summer of 2022 importantly reduced the earthworm population with effect being most pronounced for juveniles and less for adults. Both extreme weather conditions (drought in 2022 and flooding in 2023) had the least effect on no-till system with the lowest variability in earthworm abundance between years for juveniles and adults. Conservation tillage induced the most pronounced variability in earthworm abundance between years, especially in juveniles.

Although our field experiment is at an early stage of transition to alternative tillage systems, the effect on earthworms was already evident. No-till systems offered stable conditions which reduced the negative effects of severe weather and supported the most stable earthworm population even in a very dry year.

#### REGULATION OF SOIL CARBON SEQUESTRATION IN WATER-LIMITED ENVIRONMENTS: A GLOBAL REVIEW AND EXAMPLES FROM THE SOUTHWESTERN UNITED STATES

R. GHIMIRE

New Mexico State University, Las Cruces, NM, USA

Healthy soil provides the foundation for sustainable and climate-resilient agriculture. Soil health degradation and lack of comprehensive information on strategies for improving soil health and increasing soil organic carbon (SOC) sequestration have challenged agricultural sustainability in water-limited environments, such as arid and semi-arid southwestern United States. We reviewed the literature on SOC sequestration in arid and semi-arid regions with the adoption of conservation and regenerative farming practices and studied their impacts on soil health, SOC and nitrogen (N) pools, and their relationship with sustainable crop production. Our review of published global data between 1990 and 2021 comparing SOC sequestration in arid and semi-arid regions revealed a mean SOC sequestration rate of 271 kg C ha<sup>-1</sup> yr<sup>-1</sup> and 235 kg C ha<sup>-1</sup> yr<sup>-1</sup> with cover cropping and diverse crop rotation in the upper 30 cm depth. Similarly, a four-year study evaluating SOC and N pools under no-tillage corn (*Zea mays* L.) – sorghum [*Sorghum bicolor* (L.) Moench] rotation with cover cropping demonstrated improvements in soil health, SOC storage, and nutrient cycling in semi-arid soils. The SOC was 12 to 43% greater under a diverse mixture than under no cover cropping at 0–60 cm, while total labile N was 27 to 35% greater under a grass-legume mixture than no cover crop at 0–20 cm depth. Similarly, soil potentially mineralizable carbon content with cover cropping was 85.5% and 70.5 % greater than without at 10–20 and 20–40 cm soil depths. The SOC stock under various cover crops ranged between 7 to 22% greater than under no cover crops, resulting in SOC sequestration of 1.5–2.3 Mg C ha<sup>-1</sup> y<sup>-1</sup> with cover cropping. Another long-term experiment (2015-2024) evaluating SOC sequestration with cover crops and compost application showed contrasting results of cover crops and compost on various SOC and N fractions in winter wheat (*Triticum aestivum* L.)–sorghum–fallow rotation. Results of these studies will be shared with a broader audience.

#### GREENHOUSE GAS EMISSIONS IN LONG-TERM DRYLAND CROPPING SYSTEMS

U. SAINJU, B. ALLEN, J. JABRO

USDA-ARS, Northern Plains Agricultural Research Lab., SIDNEY, USA

Information is needed on the effect of long-term cropping systems on greenhouse gas (GHG) emissions in dryland conditions. The effect of 34 years of dryland cropping system was examined on N<sub>2</sub>O and CH<sub>4</sub> emissions, GHG balance (GHGB), crop yield, and yield-scaled GHG balance (YSGB) from 2016-2017 to 2017-2018 in the US northern Great Plains. Cropping systems were no-till continuous spring wheat (NTCW), no-till spring wheat-pea (NTWP), and conventional till spring wheat-fallow (CTWF). Gases were sampled twice a week to once a month throughout the year using a static chamber and flux determined. Soil C sequestration rate to a depth of 10 cm was determined from samples taken in 2012 and 2019. The N<sub>2</sub>O emissions occurred immediately after planting, fertilization, and intense rainfall from May to September in both years when the emissions was greater for NTCW and NTWP than CTWF. The CH<sub>4</sub> emissions was minimal and mostly negative throughout the year. Carbon sequestration rate was greater for NTCW than NTWP and CTWF. As a result, GHGB was lower for NTCW than NTWP and CTWF. Crop yield was greater for NTWP than NTCW and CTWF in 2016-2017, but not different among cropping systems in 2017-2018. The YSGB was also lower for NTCW than CTWF in both years. Although NTCW reduced GHG emissions, increased infestation of weeds and pests and soil acidity reduced crop yield in this cropping system. Therefore, NTWP is recommended for reducing GHG emissions while sustaining long-term dryland crop yields in the northern Great Plains, USA.

#### A SMART DYNAMIC WEB-BASED TOOL FOR THE IDENTIFICATION OF THE BEST MANAGEMENT PRACTICES: THE LANDSUPPORT BEST PRACTICE TOOL

M. BANCHERI<sup>1</sup>, A. BASILE<sup>1,2</sup>, M. ACUTIS<sup>3</sup>, M. BOTTA<sup>3</sup>, G. LANGELLA<sup>2,4</sup>, F. TERRIBILE<sup>2,4</sup>, A. PEREGO<sup>3</sup>

<sup>1</sup> Institute for Mediterranean Agricultural and Forestry Systems (ISAFOM), National Research Council (CNR), Portici, Portici, NA, ITALY

<sup>2</sup> CRISP Research Center, Department of Agriculture, University of Napoli Federico II, Portici, NA, ITALY

<sup>3</sup> Department of Agricultural and Environmental Sciences, University of Milan, Milan, ITALY

<sup>4</sup> Department of Agriculture, University of Napoli Federico II, Portici, NA, ITALY

This work presents the LandSupport - best practice tool, which allows to dynamically identify optimized agronomic solutions to pursue the objective flexibly set by the user to enhance both agricultural production and environmental sustainability. The tool is dynamic and integrates the ARMOSA process-based model, which runs on the geospatial Decision Support System LandSupport ([www.landsupport.eu](http://www.landsupport.eu)), which associates soil properties and weather data to the agricultural fields of three European case studies (Marchfeld Region in Austria, Zala County in Hungary, and Campania Region in Italy).

In a user-defined region of interest, the best practice tool simulates the effect of local management practices (N fertilization, crop residue management, tillage, irrigation) on crop production, nitrate leaching, and SOCchange. The tool provides a synthetic "Best Practice index", which combines the three model's outputs, weighted according to the end-user objectives in a multi-criteria approach. By dynamically choosing these weights, the simulated combinations of management practices are ranked to obtain the best local option.

In the early future, the process-based modeling approach will allow to simulate site-specific conditions by assimilating weather and soil data. Moreover, further practices can be easily added.

The best practice tool can contribute to several CAP requirements such as the Conditionality Obligations (Art. 12), and to Schemes for the Climate and the Environment (Art.28). Furthermore, the tool concretely approaches some issues of land degradation as required by the Sustainable Development Goals, which can be effectively reached only if we act locally in a diffuse manner, by providing easy-to-use operational tools.

#### THE RESISTANCE AND RECOVERY OF SOIL NITROGEN FERTILITY

X. TIAN <sup>1</sup>, C. ZHANG <sup>1</sup>, X.T. SONG <sup>2</sup>, X.T. JU <sup>1</sup>

<sup>1</sup> School of Tropical Agriculture and Forestry, Hainan University, Haikou, CHINA

<sup>2</sup> Research Center for Eco- Environmental Sciences, Chinese Academy of Sciences, Beijing, CHINA

How crops response synthetic nitrogen (N) applied to soils of differing fertilities is a noteworthy scientific question that remains unclear. Here we investigated the resistance and recovery of soil nitrogen (N) fertility using a long-term plot (since 2006) with various N, straw and manure fertilization regimes. We found that the high fertility soils (balanced synthetic N and manure treatment) had a significantly higher fertilizer N use efficiency (56%) with lower residual fertilizer N in soil (47 kg N ha<sup>-1</sup>) than the medium fertility soils (optimum and conventional synthetic N; 46% and 64 kg N ha<sup>-1</sup>, respectively)<sup>1</sup>. High fertility soils could provide resistance to N fertilizer reduction and maintain high yield and soil fertility even after N fertilizer supply is ceased<sup>2</sup>. High fertility soils improved the assimilability of ammonium N, which could reduce the loss of active N in soils<sup>3</sup>. Conventional synthetic N soils with long-term excessive N application continued to maintain a comparable high yield and N uptake even after N fertilizer supply was stopped, also indicating a high resistance<sup>2</sup>, which means that residual N would be used by crops directly or mineralized<sup>4,5</sup>. This effect could be applied with less N fertilizer to reduce N losses<sup>1,6</sup>. Surprisingly, re-supplying N to low fertility soils significantly increased N use efficiency to 68% and reduced residual N (31 kg N ha<sup>-1</sup>) in the soils compared to medium fertility soils (46% and 64 kg N ha<sup>-1</sup>, respectively)<sup>1</sup>. This change was associated with a large increase in root mass and root length density in the soils<sup>2,7,8,9</sup>. This illustrated the strong recovery of soils to crop productivity when resupplying N fertilizer to the lower fertility soils and the different legacy effects from historic fertilization regimes. The combination of manure and synthetic fertilizers improves soil fertility while sequestering carbon and increasing yields, which is an ideal measure for sustainable N management.

#### SOIL MICRO-FOOD WEB AS THE KEY BIOLOGICAL DRIVER OF VITAL ECOSYSTEM SERVICES FOR CROP PRODUCTION

Z YAO<sup>1</sup>, S ADL<sup>2</sup>, B ZHU<sup>1</sup>

<sup>1</sup> Institute of Mountain Hazards and Environment, Chinese Academy of Sciences, Chengdu, CHINA

<sup>2</sup> Department of soil science, University of Saskatchewan, Saskatoon, CANADA

Soil nitrogen supply and carbon accumulation are essential ecosystem services that support sustainable crop production. The soil micro-food web, which includes multitrophic interactions among various biological groups, is vital for the delivery of soil functions that underpin these ecosystem services. However, the majority of studies have only focused on certain components of the soil micro-food web, such as bacteria and/or fungi. We estimated the responses of soil micro-food webs at the aggregate level to different fertilization strategies, with the aim of understanding the impacts of soil biota on nitrogen supply and organic carbon accumulation in cropland soil. This study was based on a long-term field experiment that included recommended synthetic fertilization regime, partial synthetic nitrogen replacement with organic amendments and a zero-fertilizer control (Ctrl). Beside bacteria and fungi, nematodes and protists at higher trophic levels are important to the co-occurrence networks of the soil micro-food webs. The community composition of the taxa that significantly correlated with nitrogen supply was responsive to fertilization and important to crop yield based on random forest regression. On the other hand, the relative abundance of taxa from bacteria, fungi, protists and nematodes that correlated with carbon cycle was significantly increased by fertilization. The network complexity of the soil micro-food webs at the aggregate level was also 1-4 time higher under fertilized treatments. Compared with the contributions of bacteria and fungi to the accumulation of organic carbon, those from nematodes, protists and network complexity were also high. In conclusion, organisms of the soil micro-food web at high trophic levels play a crucial role in nitrogen supply and carbon accumulation of cropland soil. Their ecological roles should be further investigated to better utilize the biological potential of soil through improve management practices.

#### OPTIMIZING NUTRIENT USE EFFICIENCY REDUCES THE POTENTIAL FOR SOIL CARBON SEQUESTRATION OF A TEMPERATURE GRASSLAND SOIL

J. HOLLAND

AFBI, Belfast, UNITED KINGDOM

Grassland soils can potentially act as significant C sinks. Soil management practices play an important role in determining whether soil C stocks increase and net sequestration is achieved. Management effects ought to be evaluated in terms of nutrient efficiency to evaluate in a holistic manner both benefits and impacts from intensive grasslands. In this study we examine data from a long-term grassland experiment established in 1970 in Northern Ireland. This experiment has eight treatments which include an unfertilised control, inorganic fertiliser, and two types of slurry (cow and pig) at three different application rates. Common nutrient use efficiency indices were calculated and related to the soil C sequestration. The high cow slurry treatment had the largest observed soil C sequestration, however this corresponded with the lowest nitrogen (N) use efficiency (NUE). The NUE of inorganic fertiliser treatment was greater than all rates of the pig slurry and had the second highest soil C sequestered. Overall, there was a negative relationship between NUE and the soil C sequestered. Likewise, there were similar findings for the nitrogen utilisation efficiency. Efficiency indices were calculated for other nutrients (e.g. phosphorus and potassium) and related to soil C sequestration. These relationships indicate there are significant trade-offs between the efficiency of nutrient use and soil C sequestration. These results raise challenges for the management of grassland and have major implications on approaches to optimise management to achieve win: win scenarios. Indeed, this study provides information to minimise trade-offs and to sustainably balance production with climate change objectives.

**Keywords:** Nutrient use efficiency, Soil Carbon sequestration, trade-offs

#### COMPLEMENTATION BETWEEN MICROBIAL NECROMASS AND PLANT DEBRIS GOVERNS LONG-TERM BUILD-UP OF THE SOIL ORGANIC CARBON POOL IN CONSERVATION AGRICULTURE

H. HE, Y. LI, X. ZHANG

Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, CHINA

Soil organic matter is primarily originated from plant residue but occurs as a continuum from relatively fresh plant tissue to highly humified components. Nevertheless, the dynamic contribution of plant residue versus microbial necromass to the long-term build-up of the soil organic carbon (SOC) pool is still uncertain in conservation agricultural system. A 12-year conservation tillage experiment with maize additions of zero, half and full harvest was conducted in Northeast China. Soil samples in the 0-10 cm depth were collected at 1-4 year intervals. The microbial residue biomarker amino sugar and plant component biomarker lignin phenol were quantified to trace the dynamics of microbial necromass and plant debris. Temporally, the content of amino sugar increased exponentially to 21-45% and approached steady-state equilibrium after 12 years of maize straw mulching, indicating the existence of "microbial carrying capacity" under repeated plant residue addition. With prolonged duration of conservation tillage and increasing rate of maize straw return, the ratio of amino sugar to lignin phenol decreased from 6.2 to 1.7, accompanied by a decreased degree of lignin side-chain oxidation, indicating that organic input enhanced the selective retention of fresh plant lignin to a larger extent than microbial necromass. The build-up of the SOC pool under conservation tillage was critically controlled by the functional complementation of microbial- and plant-derived components. Maize straw input was able to enhance the contribution of microbial necromass to SOC stabilization by increasing fungal necromass accumulation, while the retention of lignin-like plant debris enlarged the SOC pool capacity and potentially maintained the decomposability of SOC in the long term.

### 4. Soil health in achieving the Sustainable Development Goals 4.16 133568 - Managing soil carbon and nitrogen for climate-smart and sustainable agriculture

#### COST-EFFECTIVE ADAPTATION TO WARMING IN GLOBAL CROPLANDS

J. CUI<sup>1</sup>, H. VAN GRINSVEN<sup>2</sup>, B. GU<sup>3</sup>

<sup>1</sup> Zhejiang University, Hangzhou, CHINA

<sup>2</sup> PBL Netherlands Environmental Assessment Agency, Hague, THE NETHERLANDS

<sup>3</sup> Zhejiang University, Hangzhou, CHINA

Croplands serve as the primary nitrogen source for human and contribute to nitrogen loss in the environment. Warming poses a dual threat to global food security and environmental sustainability. However, there remains a lack of consensus regarding the impact of warming on the cropland nitrogen cycle. Here we synthesized 2,289 experimental observations from global croplands and found that warming alone would decrease crop yields by 21% (95% CI, 15-27%), while increasing multiple nitrogen losses to the environment by 54-169%. By 2050, the global nitrogen harvest is projected to decline by 16 Tg ( $10^{12}$ g) annually, and nitrogen use efficiency would decrease from 47% to 38% under the warming scenario relative to the baseline scenario, leading to a 29 Tg increase in nitrogen surplus. These changes would exacerbate food crisis and nitrogen pollution, deepening regional inequality, particularly for low-income economies in Africa, Latin America, and Asia. Implementing timely and robust adaptation strategies that optimize planting date, cultivar, irrigation, and fertilization could retrieve a loss of US\$ 530 billion through avoiding damages to human and ecosystem health, with an estimated cost of US\$ 73 billion.

#### THE SOIL MICROBIAL CARBON PUMP: FROM CONCEPTUAL INSIGHTS TO EMPIRICAL ASSESSMENTS

X. ZHU, C. LIANG

Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, CHINA

Soil organic matter (SOM), as the largest terrestrial organic carbon pool, plays a pivotal role in soil organic carbon (SOC) storage and thus impacts atmospheric carbon and global climate. Our understanding of SOM genesis has shifted from the plant humus period to an ecological period emphasizing environmental and biological controls. The soil microbial carbon pump (MCP) concept emphasizes the active role of soil microbes in SOC storage by integrating the continual microbial transformation of organic carbon from labile to persistent anabolic forms. While the soil MCP concept is conceptually compelling, it lacks clear mechanistic understanding and sufficient empirical study evaluation that somewhat ineffectively link microbial necromass with SOC dynamics. Here, we interrogate the soil MCP concept by examining the asynchronous responses of microbial necromass and SOC to land-use change. Microbial necromass appeared to preferentially accumulate in the soil emerging as the dominant contributor to SOC accrual in diversified perennial bioenergy crops. Specifically, approximately 92% of the additional SOC enhanced by plant diversity was estimated to be microbial necromass carbon, and over 76% of the additional SOC resulting from the transition from annual to perennial crops was estimated to be microbial necromass. This suggests that the soil MCP was stimulated in diversified perennial agroecosystems. To assess the conversion of plant carbon into microbial necromass and the contribution of microbial necromass to SOC, we delineate two parameters: soil MCP capacity and efficacy, respectively. We hope these parameters serve as valuable metrics in evaluating SOC storage in global change studies.

**Keywords:** Soil microbial carbon pump, Soil organic carbon, Microbial necromass, Bioenergy cropping system, MCP efficacy

#### INVESTIGATING THE EFFECTS OF UREASE INHIBITORS AND NITRIFICATION INHIBITORS ON THE SOIL MICROBIOME

M. SIEDT, A.B. PONTON PAUL, M. FRANCK, I. BRILL, L. DREWS, J.T. VAN DONGEN

RWTH Aachen University - Molecular Ecology of the Rhizosphere, Aachen, GERMANY

Urease inhibitors (UI) and nitrification inhibitors (NI) are added to fertilizers to reduce emissions of ammonia, nitrous oxide, and nitrate leaching, and to increase N fertilization efficiency. However, little is known about whether UIs and NIs have unintended side effects on the soil microbiome. Here, we investigate how UIs and NIs affect the soil microbiome. Soil parameters (pH,  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ) and enzyme activities (dehydrogenase, urease, nitrification, arginine ammonification, glucosidase, acid phosphatase, arylsulfatase) were analyzed after application of different fertilization treatments in a lab incubation study. These comprised no fertilization, ammonium sulfate nitrate (ASS), ASS + NI, urea, urea + UI, urea + UI + NI. Additionally, the microbial community structure (via amplicon sequencing) and functional groups (via qPCR) will be analyzed. All experiments will be conducted with different soil types and each soil is incubated at 40% and 80% of maximum water holding capacity (WHC). At the time of abstract submission, the first results comprised the soil parameters and enzyme activities of a sandy soil at 40% WHC. It was found that the UIs reduced the activity of their target enzyme urease to about a third but also reduced the non-target process of arginine ammonification. Thus, UIs not only inhibited ammonium production from urea but also from other organic substrates. The NIs decreased the nitrate content by 18% (ASS + NI) and 21% (urea + UI + NI) in comparison to the soil fertilized without NI. The C-, P-, and S-cycle related enzyme activities were not affected by the inhibitors. The preliminary results showed that UIs and NIs have their intended effect. However, the reduced arginine ammonification rate after UI application indicated that other than the targeted soil processes might be affected. We will further investigate this in the currently ongoing project and check for unintended side effects on functional microbial groups and the microbial community structure in different soils.

#### EXPLORING NUTRIENT RECYCLING POTENTIAL OF STRUVITE AND ZEOLITES IN SOIL: INSIGHTS ON IMMEDIATE CARBON AND NITROGEN DYNAMICS

G GALAMINI<sup>1</sup>, G FERRETTI<sup>2</sup>, C ROSINGER<sup>3</sup>, S HUBER<sup>3</sup>, A MENTLER<sup>3</sup>, E DIAZ-PINES<sup>3</sup>, M GORFER<sup>3</sup>, K M KEIBLINGER<sup>3</sup>

<sup>1</sup> University of Modena and Reggio Emilia (UNIMORE), Modena, ITALY

<sup>2</sup> University of Ferrara (UNIFE), Ferrara, ITALY

<sup>3</sup> University of Natural Resources and Life Sciences (BOKU), Vienna, AUSTRIA

Intensive farming diminishes soil fertility and health, while conventional fertilization poses challenges related with environmental pollution, greenhouse gas emissions and scarce efficiency. Enhancing nutrient recycling from waste materials is therefore crucial.

A noteworthy approach involves reclaiming nutrients from wastewaters via struvite ( $\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$ ) precipitation and N-enriched zeolites, providing new materials for crop nutrition with potential of slow-release.

In a three-day laboratory incubation experiment we investigated the effects of wastewater-produced struvite and two N-enriched natural zeolites on acidic sandy loam arable soil, whereas zeolites were also tested at natural state (devoid of N), as soil amendments in the presence of struvite. Treatments were compared with the same liquid digestate used for producing them (representing a traditional organic fertilizer), and the unfertilized soil, with the aim to elucidate the short-term abiotic and biotic (microbial) drivers in N cycling and organic C turnover in soil under innovative fertilization.

All the treatments distinctly increased soil pH, with major effects on soil biogeochemical properties. The struvite quickly solubilized due to soil acidity, stimulating nitrifying and denitrifying microorganisms. Labile organic matter was released as an effect of pH increasing, where pH also governed  $\text{NH}_3$  emissions, stoichiometric relationships for C-, N- and P-acquiring exoenzymes activities, as well as the C and N microbial stoichiometry, with potentials for N immobilization. Notably, zeolites showed promising potential for  $\text{CO}_2$  and  $\text{NO}_x$  mitigation.

Struvite and zeolites enable waste revalorization and prove valuable in mitigating nutrient losses through waste treatment. This study highlights the importance of pH management, particularly when applying these materials in acidic soil, to effectively counteract losses and achieve efficient fertilization.

#### ENHANCING GLOBAL RICE PRODUCTION SUSTAINABILITY THROUGH CROP DIVERSIFICATION: A PATHWAY TO ACHIEVE THE UN 2030 SDGS

S. CAI, X. ZHAO, X. YAN

Institute of Soil Science, Chinese Academy of Sciences, NANJING, CHINA

Rice, as a primary calorie source, sustains approximately half of the global population, notably in regions grappling with malnutrition. Yet, contemporary rice cultivation systems encounter multifaceted environmental challenges, prominently nitrogen (N) losses and greenhouse gas (GHG) emissions. Concurrently, the demand for rice is anticipated to escalate from 480 million tons in 2014 to 550 million tons by 2030. To reach the United Nations' 2030 Sustainable Development Goals (SDGs) and feed the world, it necessitates a paradigm shift in rice agriculture, targeting enhanced yield outputs while concurrently mitigating environmental outflow. Compare with rice monoculture, crop diversification shows multiple advantages including increasing and stabilizing yield, and reducing environmental costs. Among them, diversified rice systems with inclusion of pulses/legumes are known to improve soil organic matter and reduce environmental N losses through biological N fixation, root exudates and higher below ground biomass. Furthermore, the low C:N ratio of legume residues bolsters the soil carbon sequestration capacity. The gaps between legume and non-legume crops in diversification rice systems suggest a noteworthy possibility for the improvement of rice-based systems. However, challenges exist in identifying globally viable croplands favor for diversified rice system and selecting optimal rotational crops suited to varied environmental conditions. Here, we endeavor to map potential lands amenable to rice rotation optimization and identify suitable rotational crops. By evaluating the environmental and sustainability benefits of these systemic alterations, we aim to furnish empirical insights into the global transition towards more sustainable rice-based cropping systems. Our findings hold the potential to guide policy and practice, contributing to the attainment of the SDGs and addressing global food security challenges.

#### CEMENT KILN DUST (CKD), DIGESTATE AND HUMIC ACID AFFECT GREENHOUSE GAS EMISSIONS AND CROP YIELD

S. CHANG, D. QIN, A. ELNAGGAR, Z. AN

Department of Renewable Resources, University of Alberta, Edmonton, CANADA

Cement kiln dust (CKD) is a byproduct of the cement industry and is often disposed of in landfills, which can be costly and environmentally unfriendly. We tested the effects of CKD (pH=12.65), a digestate (DG), and a humic acid (HA, extracted humin, humic and fulvic acids) as soil amendments on soil pH and nutrient availabilities, greenhouse gas emissions and crop yield in a wheat-canola rotation in a two-year field study on a Luvisolic soil. The following five treatments were studied: 1) Control, CK, application of conventional chemical fertilizers, 2) CKD: CKD+ chemical fertilizers, 3) CKD+HF: CKD+ 50 % of chemical fertilizers, 4) CKD+HF+DG : CKD+ 50 % of chemical fertilizers+DG, and 5) CKD+HF+HA : CKD+50 % of chemical fertilizers +HA. In year one, the application of CKD, regardless of whether applied alone or with DG or HA, increased soil pH, and had mixed effects on carbon dioxide emissions, where the application of DG increased carbon dioxide emissions, decreased nitrous oxide emissions, tended to increase methane oxidation, and increased crop yield (when CKD was applied with DG or HA). In year two, soil pH was higher in treatments where CKD was applied. All treatments increased carbon dioxide emissions but decreased nitrous oxide emissions as compared with the CK, but there were non-significant differences in methane emissions and crop yield among the treatments. The research will be conducted for two more years to assess the long-term effects of these treatments. The first two-year data suggest that CKD applied alone or in combination with DG and HA was beneficial for countering soil acidification that can result from long-term chemical fertilizer applications and reducing nitrous oxide emissions. Land application of CKD reduces waste production and has the potential to improve soil sustainability.

**NET GLOBAL WARMING POTENTIAL INDEX RATHER THAN SOIL CARBON STOCK CHANGE COULD PROVIDE BETTER UNDERSTANDING OF THE CARBON BALANCE IN SOIL SYSTEMS**

C.O. HONG

Pusan National University, Miryang, SOUTH KOREA

This study was conducted to determine the soil organic carbon (SOC) stock change factor for green manure crops that was developed by the Intergovernmental Panel on Climate Change (IPCC) Tier 2 method and compare this with the net global warming potential (GWP) index that is used to evaluate the contribution of green manuring to global warming. Four treatments were barley (*Hordeum vulgare* L.; B), hairy vetch (*Vicia villosa* R.; HV), a barley/hairy vetch mixture (BHV) and a conventional treatment (C). The aboveground biomass of green manure crops was incorporated into the soil on 25 May 2018, 26 April 2019, 29 April 2020, 30 April 2021 and 2 May 2022. Maize was transplanted as the subsequent crop after the incorporation of green manures. SOC stock decreased with green manures, even though carbon input with green manures, including B, HV and BHV, was greater than that with C. The mean value of SOC stock change factor for green manure crops, including B, HV and BHV was 0.627 and was significantly lower than that of the C. However, the net GWP also decreased with incorporation of green manure crops and the mean value of the relative net GWP index across B, HV and BHV was 0.853. These conflicting results were caused by different estimation methods between annual SOC change ( $\delta$ SOC) and net GWP. The estimation of SOC stock change using  $\delta$ SOC suggested by the IPCC method may overestimate the contribution of green manure crops to global warming. The net GWP method with comprehensive input and output of carbon in the soil system could provide better understanding of the carbon balance in soil systems. In the current study, the comparison of  $\delta$ SOC and net GWP was conducted for at one site of upland soil for 5 years. Therefore, further research on estimating the effect of green manure crops on net GWP in various types of soil for longer years should be conducted.

THE PROCESS AND MECHANISM OF 'CARBON FOR NITROGEN' EXCHANGE IN PLANTS UNDER CONTRASTING INTEGRATING DEGREE OF THE N FORM

T. LAN, X. HE, N. XIE, X. GAO

Sichuan Agricultural University, Chengdu, CHINA

This study delves deep into a key theme in terrestrial ecosystem ecology: understanding how plant growth influences soil nutrient cycling. Focusing on the interactions between microbes, soil, and plants in regulating nitrogen (N) cycling, highlights how these dynamics vary with the integrating degree of N form, particularly between crop-preferred nitrogen and soil-dominated inorganic nitrogen. Despite its importance, these mechanisms have not been systematically unraveled by the prevailing paradigm.

To address this gap, this comprehensive study investigates the complex dynamics of soil nitrogen cycling, with a special emphasis on contrasting agricultural systems: acid soil-rice systems (High integrating degree of N form, HID) versus calcareous soil-rice systems (Low integrating degree of N form, LID). The research employs a dual  $^{13}\text{C}/^{15}\text{N}$  labeling approach N labeling method in a glasshouse experiment, complemented by sophisticated  $^{15}\text{N}$  transformation modeling in both aerobic and anaerobic incubations.

The findings indicate that the LID system demonstrates a unique adaptation strategy, characterized by a greater allocation of photosynthetic carbon to the roots, a lower soil pH, specialized root architecture, and a distinct microbial community. These adaptations collectively expedite the mineralization-immobilization turnover and markedly decrease nitrogen nitrification and denitrification rates in the rhizosphere compared to the bulk soil. Consequently, this leads to an enhanced ability of the LID system plants to uptake nitrogen efficiently, directing more resources to above-ground growth. This biological strategy not only boosts photosynthetic efficiency but also mitigates ammonia volatilization and leaching losses, fostering accelerated plant growth. Moreover, these insights into the LID system's strategies highlight a crucial plant-soil carbon-nitrogen feedback mechanism, which is pivotal in sustaining plant nutrition under varying nitrogen integration conditions.

In summary, this study unveils new mechanistic insights into plant-soil carbon-nitrogen interactions under different nitrogen integration scenarios. These insights are pivotal in advancing our comprehension of nutrient cycling and microbial-soil-plant dynamics within the rhizosphere, offering valuable perspectives for sustainable agricultural practices and enhanced crop productivity in various agricultural environments.

#### BIOLOGICAL MITIGATION OF PLANT METABOLITES ON SOIL NITROUS OXIDE EMISSIONS

Y. LU<sup>1</sup>, F. WANG<sup>1</sup>, H. KRONZUCKER<sup>2</sup>, F. ZHOU<sup>3</sup>, W. SHI<sup>1</sup>

<sup>1</sup> Institute of Soil Science, Chinese Academy of Sciences, Njing, CHINA

<sup>2</sup> The University of Melbourne, School of BioSciences, Melbourne, AUSTRALIA

<sup>3</sup> Peking Univ, Coll Urban & Environm Sci, Beijing, CHINA

Plant metabolites significantly affect soil nitrogen (N) cycling, but their influence on the potential nitrous oxide (N<sub>2</sub>O) emissions has not been quantitatively analyzed across global scales. We conducted a comprehensive meta-analysis of 173 observations from 42 articles to evaluate global patterns and controls of N<sub>2</sub>O emissions under the presence of root exudates and extracts. Overall, plant metabolites had a slight promoting effect of about 10% on soil N<sub>2</sub>O emissions. However, the changes of N<sub>2</sub>O emissions induced by plant metabolites varied with different experimental conditions and properties of metabolites and soils. Primary metabolites carbohydrates (sugars, amino acids and organic acids) remarkably stimulated soil N<sub>2</sub>O emissions by 79%, while secondary metabolites such as phenolics, terpenoids and flavonoids used as biological nitrification inhibitors (BNIs) and biological denitrification inhibitors (BDIs), reduced soil N<sub>2</sub>O emissions by 41%. The mitigation effects of BNIs/BDIs were closely associated with soil texture and pH, which increased with increasing soil clay content and soil pH under acidic and neutral soils, but with decreasing soil pH under alkaline soils. The soil incubation experiments showed that three BNIs reduced N<sub>2</sub>O emissions 32-45% while the other three carbohydrates all had a stimulatory effect by 56-63%, confirming the reliability of the meta-analysis. These results highlight the potential role and application range of specific secondary metabolites in precise bio-mitigation of global N<sub>2</sub>O emissions, and may provide new biological factor parameters for N<sub>2</sub>O emission models to improve the accuracy of model predictions.

#### MICROBIAL CONTROLS ON SUCCESSION PATTERN OF RESIDUE CHEMISTRY DURING NINE YEARS STRAW DECOMPOSITION ACROSS EAST CHINA

X. WANG<sup>1</sup>, C. LIANG<sup>2</sup>, J. MAO<sup>3</sup>, Y. JIANG<sup>1</sup>

<sup>1</sup> Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

<sup>2</sup> Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, CHINA

<sup>3</sup> Department of Chemistry and Biochemistry, Old Dominion University, Norfolk, USA

Managing above-ground plant carbon inputs can pave the way toward carbon neutrality and mitigating climate change. Chemical complexity of plant residues largely controls carbon sequestration. There exist conflicting opinions on whether residue chemistry diverges or converges after long-term decomposition. Moreover, whether and how microbial communities regulate residue chemistry remains unclear. This study investigated the decomposition processes and residue composition dynamics of maize straw and wheat straw and related microbiomes over a period of 9 years in three climate zones. Residue chemistry exhibited a divergent-convergent trajectory during decomposition, that is, the residue composition diverged during the 0.5–3 year period under the combined effect of straw type and climate and then converged to an array of common compounds during the 3–9 year period. Chemical divergence during the first 2–3 years was primarily driven by the changes in extracellular enzyme activity influenced by keystone taxa-guided bacterial networks, and the keystone taxa belonged to Alphaproteobacteria, particularly Rhizobiales. After 9 years, microbial assimilation became dominant, leading to chemical convergence, and fungi, particularly Chaetomium, were the main contributors to microbial assimilation. Overall, this study demonstrated that keystone taxa regulate the divergent-convergent trajectory in residue chemistry.

#### DIVERSIFYING COVER CROPS HAD LIMITED SHORT-TERM IMPACTS ON SOIL MICROBIAL COMMUNITIES AND THE ASSOCIATED BIOGEOCHEMICAL PROCESSES

R. YE, B. PARAJULI, P. POUDEL

Clemson University, Clemson, USA

Sandy soils often have low organic carbon content, poor soil structure, and meager soil fertility. Integrating cover crops is a promising practice to improve the soils for sustainable production. However, cover crops are different with diverse functional traits, which may make the desired management outcomes unpredictable. The objective of this study was to understand how cover crop functional trait diversity (e.g., biomass production potential, root exudates rates, N fixation capacity) affects soil biogeochemical processes in the context of improving soil health, microbial diversity, and C preservation while reducing nitrogen leaching and greenhouse gas emissions. The field experiment was established in 2017 with eight treatments of winter cover crops, i.e., cereal rye, crimson clover, hairy vetch, mixture of two cover crops, mixtures of three cover crops, and no cover crop controls. Summer crops were cotton-corn rotation. Soils were collected periodically for a range of physical-biogeochemical and microbial analyses. Cover crop biomass production, residue decomposition, and greenhouse gas emissions were quantified. The preliminary data suggested that cover crops were distinguished by their functional traits. However, their ability to improve the tested sandy soils is limited in the short term, likely due to their limited biomass production (i.e., organic C inputs) constrained by low soil nutrient availability.

**Keywords:** cover crop, microbial community, decomposition, greenhouse gases, soil carbon

#### PREDICTING CO<sub>2</sub> EMISSIONS IN MAIZE FIELDS: THE IMPACT OF TILLAGE AND CLIMATE ON SOIL USING NEURAL NETWORKS

S. MOHAMMED<sup>1</sup>, A. VAD<sup>1</sup>, T. RATONYI<sup>1</sup>, A. ALKERDI<sup>2</sup>, E. HARSÁNYI<sup>1</sup>

<sup>1</sup> Debrecen University, Debrecen, HUNGARY

<sup>2</sup> Kahramanmaras university, Kahramanmaras, TURKEY

CO<sub>2</sub> emission from agricultural soil contributed significantly to the global carbon cycle, and climate change. The main aim of this research was to employ and evaluate the ability of two types of Artificial Neural Network i.e., Multi-layer Perceptron (MLP), and Radial Basis Function (ANN-RBF) in predicting CO<sub>2</sub> emissions collectively from soil of two different climate regions. CO<sub>2</sub> emissions were measured from maize fields located in two different climate regions continental (Debrecen-Hungary), and semi-arid (Karaj-Iran). Model were run by splitting the data randomly into 70% for training and 30% for testing under five scenarios (i.e., SC1, SC2, SC3, SC4, SC5). Each scenario is developed by a combination between input variables (i.e., soil temperature (T), soil moisture (M), date of measurement (SD), soil management (SM)), once as factors and once as covariate. Both algorithms MLP and RBF were able to predict CO<sub>2</sub> in a very good level, where the model performance (NSE) for MLP ranged between 0.62-SC5 (acceptable) and 0.87-SC2 (very good). While the NSE for RBF ranged between 0.62-SC1 (acceptable) and 0.71-SC2 (good). For both algorithms, the highest correlation (r) was recorded in SC2 (r MLP = 0.93, r ANN-RBF =0.84).

#### LONG-TERM EFFECTS OF NITROGEN FERTILIZER INPUT ON N<sub>2</sub>O AND N<sub>2</sub> EMISSION IN NORTH CHINA PLAIN

X. LI

center for agricultural resource research, IGDB,CAS, shijiazhuang, CHINA

High nitrogen (N) input to soil could cause higher nitrous oxide (N<sub>2</sub>O) emission, i.e. a higher N<sub>2</sub>O/(N<sub>2</sub>O+N<sub>2</sub>) ratio, through an inhibition of N<sub>2</sub>O reductase activity and/or a decrease of soil pH. We assumed these two mechanisms were the immediate and long-term effects of N input on N<sub>2</sub>O emission, respectively. The immediate effect can be eliminated by decreasing N input, but not for the long-term effect. It is therefore important to separate these two effects for mitigating N<sub>2</sub>O emission. To this end, soil samples from surface to 5m depth soil profile were collected from a long-term N fertilization experiment field with two N application rates, i.e. 600 kg N ha<sup>-1</sup> year<sup>-1</sup> (N600) and no fertilizer N input (NO). An external N addition was conducted for each subsample in the laboratory incubation study to produce another two treatments, which were denoted as N600+N and NO+N treatments. The results showed that the combined immediate and long-term effects led to an increase of N<sub>2</sub>O/(N<sub>2</sub>O+N<sub>2</sub>) ratio by 6.8 percent, 32.6% and 67.4% of which could be explained by the immediate effect and the long-term effect of N input. Meanwhile, the long-term effects were significantly positively correlated to soil organic carbon (SOC). These results indicate that excessive N fertilizer input to soil could lead to increased N<sub>2</sub>O emission if the soil had a high SOC content. The long-term effect of N input on the N<sub>2</sub>O/(N<sub>2</sub>O+N<sub>2</sub>) ratio especially need to be taken into account when predicting soil N<sub>2</sub>O emission under the global environment change scenarios.

**CARBON AND NITROGEN CONTENT AFTER 35 YEARS OLD TEA CULTIVATION IN WET TROPICAL REGION,  
WEST SUMATRA INDONESIA**

Y. YULNAFATMAWITA<sup>1</sup>, S. YASIN<sup>2</sup>, Z.A. HARIS<sup>3</sup>

<sup>1</sup> Universitas Andals, Padang, INDONESIA

<sup>2</sup> iversitas Andals, Padang, INDONESIA

<sup>3</sup> Universitas Putra Indonesia, Padang, INDONESIA

Research on aggregate fractionation as well as the carbon and nitrogen association on it was conducted under a tea plantation in a wet tropical region (100°36'24.9"-100°39'26.99" E and between 0°58'19.11" – 1°1'18.83") in West Sumatra, Indonesia. The research aimed to determine organic carbon (OC) and total nitrogen (TN) content associated with different aggregate sizes. The soil was sampled from 3 soil depths (0-10, 10-20, 20-40 cm) at 5 different slope levels under a tea plantation 36 years old. The parameters analyzed were soil texture, bulk density, and total soil pore besides OC and TN. For OC and TN, the soil was fractionated into 3 different sizes (<250 µm = micro, 250-500 µm = meso, and >500-2000 µm = macro) aggregates. The results showed that soil texture in the area was classified into clay loam - silty clay loam, BD was < 0.9 g/cm<sup>3</sup>, and TSP was >70%. Based on aggregate fractionation, it was found that the percentage of macro > meso > micro aggregates. Soil OC was found to be the highest under micro- (5.16%) and then followed by macro- (4.88%) and meso- (4.74%) aggregates. Among the slopes, soil OC content tended to increase by increasing slope level from 0-8% to 15-25% and then decreased by continuing slope increase until >45%. As OC, soil N content was also found the highest within micro-aggregates, and then meso- and macro-aggregates. However, among the slopes, N content was not followed by OC content, it decreased with increasing slope levels. The N content was not significantly different between meso and macro aggregates. It can be concluded that either C or N was found the highest within aggregate <250 µm.

<sup>4</sup> Incitec Pivot Fertilisers, Seabreeze Parade, North Shore, Victoria, AUSTRALIA

In the context of a growing global population, the increased reliance on synthetic nitrogen (N) fertilizers for global food production appears inevitable. Unfortunately, nearly half of the applied fertilizer N in agricultural systems is lost to the environment, posing significant threats to human health, environmental quality, and ecosystem services. Enhanced efficiency fertilizer (EEF) technology offers promise in mitigating N losses to the environment. EEFs regulate N release based on external stimuli (controlled-release fertilizers) and inhibit enzyme activities involved in processes that lead to N losses (urease and nitrification inhibitors). This presentation will explore the current limitations of EEFs and underscore the pressing need for breakthroughs in EEF development. Achieving this goal demands collaborative research efforts across multiple disciplines, including agronomy, soil science, synthetic chemistry, chemical engineering, plant physiology, and plant biochemistry. We argue that recognizing and quantifying the social costs avoided through EEF adoption are imperative to incentivize the use of innovative N fertilizers. This approach will not only prevent substantial expenditures on N pollution mitigation but also ensure global food security.

#### UNVEILING THE MECHANISM FOR THE DIVERGENT IMPACT OF NITROGEN FERTILIZATION ON CH<sub>4</sub> EMISSIONS FROM RICE PADDIES

H. LEE <sup>1</sup>, H. KANG <sup>2</sup>

<sup>1</sup> Leibniz University Hannover, Hannover, GERMANY

<sup>2</sup> Yonsei University, Seoul, SOUTH KOREA

Rice, a vital staple food for 3.8 billion, faces challenges due to population growth and environmental concerns related to nitrogen fertilizers (NF) and methane (CH<sub>4</sub>) emissions from paddies. This study employs field experiments and a global meta-analysis to investigate the factors influencing greenhouse gas intensity (GHGI) in rice paddies, aiming to optimize NF application rates for sustainable rice production while reducing greenhouse gas (GHG) emissions. Cumulative CH<sub>4</sub> emissions in Hwaseong with NF application rates of 135 and 180 kg ha<sup>-1</sup> (N1.5 and N2) were significantly lower than those with 0 kg ha<sup>-1</sup> (Control, NO). However, in Miryang and Wanju, cumulative CH<sub>4</sub> emissions increased in response to all NF application rates. Compared to N1, N1.5 in all regions showed a decreased or no change in global warming potential (GWP) and exhibited a more significant reduction in greenhouse gas intensity (GHGI). Additional NF application of 45 kg ha<sup>-1</sup> could reduce GHG emissions and improve crop yields. The methanogenesis ratio significantly increased with NF application rates in Miryang and Wanju, while in Hwaseong, it was considerably lower than NO and N1 due to a significant increase in methanotrophs (pmoA) transcript abundance at N1.5 and N2. Cyanobacteria were a predominant microbial community in Hwaseong, occupying approximately 21-42% due to its relatively high concentration of initial total nitrogen (TN) (1.32 g kg<sup>-1</sup>) compared to the other regions (0.71 and 0.88 g kg<sup>-1</sup>, Miryang and Wanju, respectively). Cyanobacteria showed increased activity for photosynthetic function in high initial TN concentration, encouraging improved methanotroph activity. In a global-scale meta-analysis comprising 192 observations, CH<sub>4</sub> emissions from NF application significantly decreased as initial TN concentration increased (P=0.004). This study provides new evidence highlighting the determinant role of initial TN concentration in NF usage for reconciling global warming and food security.

#### NUTRIENT RUNOFF AND SOIL STABILITY IN A LONG-TERM AGRICULTURAL EXPERIMENT IN CENTRAL-SOUTHEAST NORWAY

I. EISCHEID, T. HENRIKSEN

Norwegian Institute of Bioeconomy Research (NIBIO), Kapp, NORWAY

We present soil property changes and differences in nutrient losses of six contrasting cropping systems in a 30 year long-term agricultural field experiment in central-southeast Norway. This includes three conventional systems with varying degrees of tillage intensity, use of cover crops and grass ley, as well as three organic systems that differ in the amount of grass ley in the rotation, from one in four years to three in four years. The soil in this area is a Endostagnic Cambisol with loam and silty sand textures. The climate is humid-continental with a mean annual precipitation of 600 mm and temperature of 3.6 °C. Surface runoff and nutrient leaching is measured for each crop rotation and cropping system (n=48) on a monthly basis. Our results show that reduced tillage and high biomass inputs (cow manure in combination with grass ley rotation or no removal of stubble and use of cover crops) significantly improved aggregate stability and led to a long-term reduction of runoff losses for sediments and phosphorous. In contrast, losses of dissolved nitrogen were more dynamic and were influenced by year-to-year variation such as the amount of fertilizer inputs, establishment of cover crops or grass ley and precipitation patterns. When including the ratio of human consumable food produced to the amount of nutrient loss, the system with cover crops and reduced tillage outperformed both the most intensive cropping system with autumn ploughing and the systems that included grass ley in their rotations.

#### AGRICULTURAL NITROGEN BALANCE IN OECD COUNTRIES: CAUSES AND IMPACTS ON NITROGEN EMISSIONS

L. JIYEON<sup>1</sup>, K. PILJOO<sup>2</sup>

<sup>1</sup> Leibniz University Hannover, Hannover, GERMANY

<sup>2</sup> Gyeongsang National University, Jinju, SOUTH KOREA

Excessive nitrogen (N) outflowing from agricultural land to surrounding environments can destroy the ecosystem balance and cause serious environmental pollution, endangering many living organisms. The Organization for Economic Co-operation and Development (OECD) developed a soil surface nutrient balancing system and made it mandatory for member countries to report annual nutrient budgets. Nitrogen balance varies across member countries and some have significant N balance. To evaluate changes in N balance in member countries and to figure out the reason for the changes, the 30-year N budget reports published by 35 OECD countries were reviewed and key factors consisting of N budgets were analyzed along with other N-related agri-environmental indicators. Among the three factors determining N balance (agricultural land area, N input, and N output), agricultural land area decreased in most OECD countries, negatively affecting N balance reduction. However, the OECD's average N balance highly decreased from 91 to 46 kg ha<sup>-1</sup> over the last 30 years due to the significant decrease in N input through inorganic fertilizers and manure, especially in EU countries with high N input levels. Inorganic fertilizer and manure N inputs showed a strong positive relation with crop and forage N output, respectively. Nitrogen output did not meaningfully change. This decrease in N balance could have been achieved due to a significant improvement in N use efficiency. In comparison, in Japan and Korea, the N balance slightly increased and they became the highest N balance country recently. A higher N balance led to lower N use efficiency and higher ammonia (NH<sub>3</sub>) and nitrous oxide (N<sub>2</sub>O) emission intensities. More densely populated countries with smaller agricultural land per capita (ranging from 0.03 to 0.47 ha capita<sup>-1</sup>) showed a higher N balance (228–80 kg ha<sup>-1</sup>), presumably due to higher N input for more agricultural production on limited land. Therefore, highly populated countries with small arable land areas per capita might need multilateral efforts to alleviate agricultural N balance.

#### CHARACTERIZATION OF MICROBIAL COMMUNITIES ASSOCIATED TO SOIL AND ROOTS OF PHYTOSTABILIZING PLANTS ON SARDINIAN ABANDONED MINING AREAS

M. MANDARESU<sup>1,2</sup>, E. TAMBURINI<sup>1</sup>, G. CAPPAL<sup>2</sup>

<sup>1</sup> University of Cagliari - Department of Biomedical Sciences, Cagliari, ITALY

<sup>2</sup> University of Cagliari - Department of Civil-Environmental Engineering and Architecture, Cagliari, ITALY

Abandoned mining areas are a crucial worldwide environmental problem posing serious risks for human health and ecosystems. The area of Sulcis-Iglesiente (South–West Sardinia) was one of the most important European mining district for centuries.

The physical, chemical, and biological constraints encountered in mine substrates severely limit plant colonization and growth. Moreover, the level of contaminations in these sites have been found to alter the structure of microbial communities and decrease their biodiversity.

Phytostabilization technology implies the creation of a vegetation cover for the long-term immobilization of metals within the plant rhizosphere, limiting the ecosystem exposure. Employing plant growth-promoting bacteria (PGPB) in phytoremediation processes is an effective technique that can enhance plant biomass production and stabilize metals.

The aim of this research is to improve the bioaugmentation assisted phytoremediation of these heavily polluted sites with the study of the interaction between plants spontaneously growing in mine area and microbial communities associated with.

In this study, the microbial communities and the enzymatic activity has been characterized. The analysis in progress to define the microbial communities and the toxicity of different sites are Next Generation Sequencing of rRNA genes, titre of heterotrophic bacteria and fungi, dehydrogenase assay and total metals. Furthermore, we are selecting PGPBs for the improvement of the phytoremediation technology based on common traits such as production of indole acetic acid, ACC deaminase enzyme, siderophores, phosphate solubilization and metal tolerance.

Taking into account the metals contamination and the autochthonous plants present in these ecosystems chronically impacted by mining activities, this study allows us to enrich the knowledge regarding the microbial communities with a deepened analysis on PGPBs with the final objective of improving the phytostabilization technology.

#### MONITORING OF CHEMICAL SPECIES IN SOILS, WATERS, AND PLANTS NEAR THE ACTIVE COPPER MINE TAILING DAM OVEJERIA (CENTRAL CHILE).

Y. TAPIA, O. SALAZAR, A. JOVEN, A. CELEDON, A. GARCIA

Universidad de Chile, Santiago, CHILE

Chile, the world's largest copper producer, generates massive amounts of mine tailings that are a source of ongoing environmental concern for local communities. The main objective of this work is to evaluate the concentration of As, Cd, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Zn and SO<sub>4</sub><sup>2-</sup> in soils, water, and vegetation in the communities surrounding the Cu Ovejera mine tailings dam, in central Chile. Soils, water and plants samples were collected from the towns of Chacabuco, Huechún, Huertos Familiares, Punta Peuco and Santa Matilde, which are located at 3 to 8 km from the mine tailings site, operated by CODELCO since 1999. The results showed that the levels of metals/metalloids and SO<sub>4</sub><sup>2-</sup> in water (pH 6.7-7.9) met both WHO limits and Chilean water quality standards for multiples uses. In soil (pH 7.7-8.4), total and available concentrations of metals/metalloids did not exceed international reference values. Plants with acceptable levels of metals and S were Citrus limon, Eucalyptus, Schinus molle, Prunus persica, Medicago sativa, Citrus sinensis, and Ficus carica. The only species with Fe content well above the reference value and with high concentrations of other metals (Cu, Mn, Mo, and Pb) was Acacia caven. The concentrations of chemical species determined between 2015-2018, in different media and locations near the active Cu tailings dam Ovejera, in Central Chile, allow to conclude that in general the levels are comparable to national and international references and do not indicate contamination.

Floodplain soils provide a wide range of ecosystem services including filtration, but they also face high anthropogenic pressure from economic activities. Emerging environmental contaminants (EECs) are gradually starting to appear alongside traditional such as heavy metals (HMs). The occurrence, fractions, potential ecological and human health risks of 4 HMs (Cd, Cu, Pb, Zn) and 3 EECs (Li, Ba, B) originating from historical mining in Fluvisols of various ecosystems (arable lands, grasslands, riparian zones) were investigated at 19 localities along the Štiavnica river in Slovakia. For all contaminants, we recorded at least one locality exceeding the limit value for total content. The contaminants partitioning in the different fractions revealed that Cd, Zn, and Pb were mainly associated with the exchangeable and reducible fractions, Cu with the oxidisable, and EECs residual fraction. The highest contamination factor was calculated for Cu (39.8), followed by Pb (27.4), Zn (18.2), Li (15.6), Cd (7.2), B (2.3), and Ba (2.0). We found out possible potential health risks associated with Pb and Li exposure for children. The highest hazard quotient was calculated in children group for Pb (9.51), followed by Li (1.48), Cd (0.31), Cu (0.17), Zn (0.13), Ba (0.12), and B (0.004). The soil properties were selectively correlated with the contaminant fractions. Based on the ANOVA results, the effect of different ecosystem types on HM and EEC fractions was revealed.

TOXICITY RESPONSES OF BRASSICA RAPA TO CERIUM, GADOLINIUM, AND YTTRIUM IN TWO ACIDIC SOILS WITH CONTRASTING TEXTURES

P H WU <sup>1</sup>, K C YEH <sup>2</sup>, Z Y HSEU <sup>1</sup>

<sup>1</sup> 1Department of Agricultural Chemistry, National Taiwan University, Taipei, TAIWAN

<sup>2</sup> Agricultural Biotechnology Research Center, Academia Sinica, Taipei, TAIWAN

Rare earth elements (REEs) have been considered as emerging contaminants, but little is known about their bioavailability and physiological effects in soil-plant system. Therefore, the purpose of this study was to investigate the effects of different dosages of cerium (Ce, 0-100 mg/kg), gadolinium (Gd, 0-120 mg/kg), and yttrium (Y, 0-100 mg/kg) on Chinese cabbage (*Brassica rapa*), including biomass, REEs uptake, photosynthetic pigments (chlorophyll a + b and carotenoids), triphenyl-tetrazolium chloride (TTC) reduction, and proline content growing on two acidic soils with different textures (silty clay loam and sandy loam). The tested crops were grown for 35 days, and soil pore water was collected through the Rhizon moisture samplers. In the silty clay loam soil, the crop shoot biomass increased significantly ( $p < 0.05$ ) at the dosages of 25 mg/kg Gd and 25 mg/kg Y but decreased at 120 and 100 mg/kg, respectively. Regardless of the dosage levels of Gd and Y, the crop biomass was consistent in the sandy loam soil with different REEs treatments. In addition, Ce had no significant effect on biomass in these two soils. All photosynthetic pigments decreased with increasing dosages of REEs in soils, suggesting that REEs reduced the functions of photosynthesis. The TTC reduction results indicated that the respiration of crop was significantly enhanced at the dosages of 30 and 60 mg/kg Gd in the silty clay loam soil, but was significantly inhibited at the dosages of 25, 50, and 100 mg/kg Ce in the sandy loam soil compared with the blank treatment. The change of proline concentration was corresponding to that of TTC reduction in all treatments. The concentration of REEs in roots and shoots increased with increasing concentration of REEs in the soils. Furthermore, the LA-ICP-MS analysis showed that the hotspots of REEs overlapped with those of Fe and Al. Hence, the toxicity responses of *Brassica rapa* to Ce, Gd, and Y depended on the dosages of REEs and soil textures.

#### AGRICULTURAL CARBON NEUTRALITY AND HEALTH REGULATION OF BLACK SOIL

Y. ZHANG, J. QU, B. ZHANG, L. WANG

Northeast Agricultural University, Harbin, CHINA

Black soil is a precious soil resource on Earth. As one of the only four major black soil regions in the world, the northeast region of China is an important base of grain production. However, due to the inappropriate use of agricultural inputs and unreasonable farming, the reduction of organic content, the aggravation of non-point source pollution, the degradation of soil function, and the thinning of the surface layer have been appeared in black soil of cold region, posing significant challenges for sustainable development of black soil. Therefore, it is urgent to carry out the health control of black soil in order to achieve the carbon neutrality. Herein, we created a variety of novel multi-functional organic fertilizers, which increased the content of soil organic matter by 15% and effectively reduced the application of chemical fertilizer. Meanwhile, a green and low-carbon in-situ directional restoration technology of agricultural chemical residues in black soil was established, and the concept of 'remediation while production' was innovatively proposed. Moreover, we have developed the technology of black soil topsoil reservoir expansion to alleviate degradation of ecological function, effectively using agricultural waste and reducing gas emissions of agricultural greenhouse. Additionally, we broke through the limitation of low temperature environment and constructed decomposition bacteria of straw in the high cold area, exploring the synergistic way to rapid decompose rice straw and construct fertile soil layer. Finally, we studied the measurement technology of regional scale agricultural greenhouse gas emission and the quantification estimation of greenhouse gas carbon sequestration and emission reduction in farmland scale, which explored the carbon measurement method of agricultural industry activities oriented to carbon trading. The above-mentioned technologies were widely demonstrated and achieved excellent economic and social values. In this study, a series of control techniques for black soil were proposed, which provided promising strategies for ensuring black soil health in cold regions, strengthening food security, and promoting carbon neutrality in the world.

#### THE FATE OF MULTIPLE PERSISTENT ORGANIC SOIL POLLUTANTS INTRODUCED VIA BIOBASED FERTILIZERS SIMULTANEOUSLY ASSESSED BY NOVEL SCREENING METHODS

B. JANSEN, Y. DONG, S. DAS, E. DE RIJKE, J. PARSONS

University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, THE NETHERLANDS

The linear use of synthetic fertilizers has proven indispensable to provide sufficient food for a growing world population but suffers from serious issues including soil acidification and soil degradation. As a result, the last decade has seen an increasing attention for the use of nutrient rich waste streams, such as crop and animal remains, to produce biobased fertilizers (BBFs) as an alternative fertilizer source. In the EU funded LEX4BIO project we study the potentials and risks of large scale BBF application. A primary concern is the potential introduction of persistent organic pollutants to the soil via BBFs, as well as the effects of the introduction of BBFs on legacy persistent organic pollution in the soil. In both cases this concern potentially covers a wide range of chemical classes contained within complex BBF matrices. As a result, screening for pharmaceuticals and pesticides in BBFs themselves as well as in soils after BBF application poses a challenge. To overcome this, we developed an advanced screening method to simultaneously screen for a broad suite of pharmaceuticals and pesticides in BBFs and in BBF amended soils [1,2]. It consists of a QuEChERS-extraction followed by UHPLC-QTOF-MS/MS analysis. We successfully applied the new methodology using target analysis and suspect screening to scan for > 500 pharmaceuticals and pesticides in total, in 15 BBFs and several soils from field-trials. The results indicate a very limited presence of pollutants in the BBFs and soils [1,2]. Given the varied nature of the BBFs they provide a complex range of organic matrices with which those pollutants can interact, in addition to the soil matrix itself after BBF application. Indeed, we found that the introduction of the BBFs affected the bioavailability of organic contaminants introduced via the BBFs as well as those already present in the soil.

#### PFAS AND PPCP IN BIOSOLIDS FROM MUNICIPAL WASTEWATER RESOURCE RECOVERY FACILITIES IN THE USA

H. LI <sup>1</sup>, Z. XU <sup>1</sup>, Q. DONG <sup>1</sup>, W. ZHANG <sup>1</sup>, Q. HUANG <sup>2</sup>, Y. WANG <sup>2</sup>, S. OZA <sup>3</sup>, K. BELL <sup>3</sup>, J. NORTON <sup>4</sup>

<sup>2</sup> University of Georgia, Department of Crop and Soil Sciences, Griffin, GA, USA

<sup>3</sup> Brown and Caldwell, Charlotte, NC, USA

<sup>4</sup> Great Lakes Water Authority, Detroit, MI, USA

Per- and polyfluoroalkyl substances (PFAS), and pharmaceuticals and personal care products (PPCP) are considered the major classes of contaminants of emerging concern frequently found in the soil environment, owing to their wide range of daily use in many products. These contaminants are commonly released to municipal wastewater resource recovery facilities (WRRF), and the current treatment processes cannot efficiently remove these contaminants from WRRF. Therefore, PFAS and PPCP could be concentrated in the biosolids of WRRF. The subsequent land application of biosolids for beneficial reuse could disseminate PFAS and PPCP to the soils of home gardens and agricultural lands. In this study, we collected biosolids samples from twelve WRRF across the United States, and conducted target analysis for 41 PFAS and 36 PPCPs in the biosolids samples (including both solid and liquid fractions) using liquid chromatography coupled to tandem mass spectrometry. The results showed that all biosolids samples contained both PFAS and PPCP with the concentration range from ng/g to ug/g levels. More than 72 % of the target PPCP and 51% of the PFAS could be quantified in the biosolids samples. For the PPCP and PFAS with highly hydrophilic nature, these contaminants were more frequently detected in the liquid fraction, rather than in the solid fraction. Most PFAS found in the biosolids were PFAS precursors. The removal efficiencies of PPCP and PFAS are examined for the specific biosolids treatment process.

**PER- AND POLYFLUOROALKYL SUBSTANCES (PFAS) IN THE SOIL-PLANT SYSTEM: SORPTION, ROOT UPTAKE, AND TRANSLOCATION**

C. LUO

Guangzhou institute of geochemistry, CAS, Guangzhou, CHINA

Per- and polyfluoroalkyl substances (PFASs) are ubiquitous in the environment but pose potential risks to ecosystems and human health. The soil-plant system plays an important role in the bioaccumulation of PFASs. Because most PFASs in the natural environment are anionic and amphiphilic (both lipophilic and hydrophilic), their sorption and accumulation behaviors differ from those of neutral organic and common ionic compounds. In this study, we investigate processes affecting the availability of PFASs in soil after analyzing the potential mechanisms underlying the sorption and uptake of PFASs in the soil-plant system. We found that the root concentration factor of PFASs for plants grown in soil was not significantly correlated with hydrophobicity, whereas the translocation factor was significantly and negatively correlated with PFAS hydrophobicity regardless of whether plants were grown hydroponically or in soil. Further research on the cationic, neutral, and zwitterionic forms of diverse PFASs is urgently needed to comprehensively understand the environmental fates of PFASs in the soil-plant system. Additional research directions are suggested, including the development of more accurate models and techniques to evaluate the bioavailability of PFASs, the effects of root exudates and rhizosphere microbiota on the bioavailability and plant uptake of PFASs, and the roles of different plant organelles, lipids, and proteins in the accumulation of PFASs by plants.

#### IMPACTS AND MECHANISMS OF RYEGRASS RHIZOSPHERE ON THE IN-SITU MICROBIAL DEGRADATION OF TRI(2-CHLOROETHYL) PHOSPHATE (TCEP)

L. JIANG

Guangzhou institute of geochemistry, CAS, Guangzhou, CHINA

Tri(2-chloroethyl) phosphate (TCEP) is a typical chlorinated organophosphate widely present in soil, posing a potential threat to human health. Microorganisms play a crucial role in the remediation of soil organic phosphate contamination. The rhizosphere serves as a hotspot for microbial activity and holds advantages in removing soil TCEP pollution, but its role and potential mechanisms in TCEP microbial degradation remain unclear. This study utilized DNA stable isotope probing (DNA-SIP) to investigate the role of ryegrass rhizosphere in the microbial degradation of TCEP. The results showed that the rhizosphere could enhance the degradation efficiency of TCEP (1.8 times higher than in non-rhizosphere treatment). Through DNA-SIP, degradation microorganisms from 13 genera were identified, with 12 genera being linked to TCEP biodegradation for the first time. The alpha-diversity of TCEP degraders was significantly higher in the rhizosphere than in non-rhizosphere treatment. Further analysis of TCEP metabolic product suggested that TCEP could undergo hydrolysis of phosphate ester bonds, reduction, oxidative dechlorination, and methylation reactions. Based on gene abundance data, the phosphoric acid ester hydrolysis, oxidative dechlorination, and methylation pathways coexist in both non-rhizospheric and rhizospheric treatments, and rhizospheric environment plays a beneficial role in the enrichment of related genes. This study elucidates the role played by the rhizosphere in the in-situ remediation of TCEP in contaminated soils.

#### NANO OR NOT, WHAT DIFFERENCE DOES IT MAKE? A STABLE ISOTOPE LABELING APPROACH TO ASSESS FATE AND BIOAVAILABILITY OF METALLIC ENGINEERED NANOPARTICLES IN SOIL

C. COUTRIS <sup>1</sup>, K.A. JENSEN <sup>2</sup>, P.A. RIVIER <sup>1</sup>, S. DEVILLIER <sup>1</sup>, A. GEORGANTZOPOULOU <sup>3</sup>, S. KUEHR <sup>3</sup>

<sup>1</sup> Norwegian Institute of Bioeconomy Research (NIBIO), Department of Bioresources and Recycling Technologies, Ås, NORWAY

<sup>2</sup> Norwegian University of Life Sciences (NMBU), Faculty of Environmental Sciences and Natural Resource Management, Ås, NORWAY

<sup>3</sup> Norwegian Institute for Water Research (NIVA), Department of Ecotoxicology and Risk Assessment, Oslo, NORWAY

By the time they enter soils, engineered nanomaterials (ENM) have undergone physicochemical transformations and may no longer resemble the pristine materials which have been thoroughly investigated during two decades of nanotoxicology research.

Is the behavior of environmentally relevant chemical forms of ENM different from that of other metallic species present in soils? Are they more available to soil organisms than their naturally occurring counterparts? The present study aimed at answering these questions, through the use of isotopically enriched ENMs, which could be traced at low concentrations in soil microcosms, despite high natural metallic background.

The relevance of the chemical forms was ensured by introducing isotopically enriched <sup>109</sup>Ag, <sup>68</sup>ZnO and <sup>46</sup>TiO<sub>2</sub> ENM to a wastewater treatment plant and using the resulting sewage sludge (final sink for most ENM) as amendment in soil microcosms with earthworms. The sludge application rate to soil was similar to that used in agriculture and the experiment lasted for a month. Protocols using inductively coupled plasma mass spectrometry were developed for determination of isotope ratios in complex matrixes, such as soil and organisms.

For <sup>109</sup>Ag ENM, the dissolved fraction in soil (i.e. the most easily accumulated in organisms) was extremely low and comparable to that of Ag naturally present in soil, and transfer factors to earthworms were similar to those of natural Ag. For <sup>46</sup>TiO<sub>2</sub> ENM, the transfer to earthworms was negligible, similarly to what was observed for natural Ti. While no difference in behavior and bioavailability was observed between ENM and their naturally occurring counterparts for Ag and Ti, different results were obtained for Zn. The dissolved fraction for <sup>68</sup>ZnO ENM was 3-5 times higher than for Zn forms naturally present in soil, and transfer factors to earthworms twice those of natural Zn.

Overcoming long-standing challenges related to environmental relevance of chemical forms and concentrations in nanotechnology studies, the approach provides valuable insight into behavior and impacts of environmentally relevant forms of ENM in soils.

#### EXPLORING THE INTERPLAY: MICROPLASTICS AND ANTIBIOTIC RESISTANCE ACROSS EUROPEAN SOILS

A. VISCA, E. CLAGNAN, L. DI GREGORIO, M. COSTANZO, A. BEVIVINO

ENEA, Biotechnologies and Agroindustry Division, Department for Sustainability, Rome, ITALY

Antibiotic resistance (AR) is now recognized by the World Health Organization as one of the major threats to human health. The root of AR can be traced back to the One Health link, that recognize that antibiotics use for human and animal health, and the environment, are interconnected and contributing to its spread. The soil is a sink for the selection of antibiotic resistance genes (ARGs) and bacteria, due to the continuous input of legacy and emerging contaminants. The increasing amount of microplastics (MPs) present in the environment raised further concerns regarding their role in promoting ARGs. Bacterial communities on the plastisphere are selected according to plastic properties; they colonize MPs surfaces and proliferate. In this work, the data from LUCAS dataset (885 soil sample from different EU countries) was re-elaborated using the Emu tool to characterize the microbial community at genus/species level. The functional annotation was performed through PICRUSt2 using a novel tool to format the Emu output. Interestingly, 96 ARGs and 6 MPs pathways was found and their correlations were explored. This study highlights how the fate of ARGs in the soil remains a central concern, and how the ever-increasing presence of MPs poses a risk of further exacerbating the severity of the AR problem. This study was funded by the Italian project SOIL-HUB (D.M. 37072/7303/18—28/12/2018, D.M. 35851—5/11/2019).

ENDOGENOUS BIOHYDROGEN FROM A RHIZOBIUM-LEGUME ASSOCIATION DRIVES MICROBIAL BIODEGRADATION OF POLYCHLORINATED BIPHENYL IN CONTAMINATED SOIL

Y. TENG, Y. XU, Y. LUO

Institute of Soil Science Chinese Academy of Sciences, Nanjing, CHINA

Endogenous hydrogen is produced through rhizobium-legume associations in terrestrial ecosystems worldwide through dinitrogen fixation. In turn, this gas may alter rhizosphere microbial community structure and modulate biogeochemical cycles. Symbiotic rhizobium-legume associations are also important in the elimination of environmental persistent organic pollutants (POPs) from soils. However, very little is understood about the role that this hydrogen leaking to the rhizosphere plays in shaping the POPs degrading microbes in contaminated soils. Here, we combined DNA-stable isotope probing (DNA-SIP) with metagenomics to explore how endogenous hydrogen from the symbiotic rhizobium-alfalfa association drives the microbial biodegradation of tetrachlorobiphenyl PCB 77 in a contaminated soil. The results showed that PCB77 biodegradation efficiency increased significantly in soils treated with endogenous hydrogen. Based on metagenomes of  $^{13}\text{C}$ -enriched DNA fractions, active PCB degraders are diverse in polluted soil and endogenous hydrogen selected bacteria harboring PCB degradation genes. Functional gene annotation allowed the reconstruction of several complete pathways for PCB catabolism, with different taxa conducting successive metabolic steps of PCB metabolism. Key taxa growing hydrogenotrophically by using electrons derived from hydrogen for carbon fixation were demonstrated to play an important role in promoting the degradation of PCB77 by endogenous rhizosphere hydrogen. In particular, the enrichment of hydrogenotrophic *Pseudomonas*, *Magnetospirillum* and likely other taxa encoding biphenyl oxidation genes drives PCB biodegradation primarily through endogenous hydrogen in the rhizosphere. This study proves that endogenous hydrogen is a significant energy source for active PCB-degrading communities and suggests that elevated hydrogen can influence the microbial ecology and biogeochemistry of the legume rhizosphere. In a broader view, this work aimed to contribute new knowledge on the relationships between biohydrogen and specific functional soil microbes in the rhizosphere and inform future rhizobium-legume system biohydrogen metabolism efforts in the bioremediation of terrestrial environments.

#### IS IT SAFE TO IRRIGATE CROPS WITH TREATED WASTEWATER? LONG-TERM MONITORING STUDY AND EXPOSURE ASSESSMENT

B. CHEFETZ, E. BEN MORDEHAY

The Hebrew University of Jerusalem, Rehovot, ISRAEL

Irrigation with treated wastewater is a growing agricultural practice. However, this practice exposes the agricultural ecosystem to organic pollutants that were not completely removed during the wastewater treatment. Once introduced into the field these pollutants may be taken up by plants and introduced into the food chain. The current study used Israel as a living lab (case study) to estimate the unintentional exposure of the population to organic pollutants originating from wastewater. We used up-to-date dietary data and measured the concentrations of organic pollutants in produce representing ~75% of the diet. Based on that exposure was calculated. Human health concerns were estimated using two approaches: the acceptable daily intake (ADI) and the threshold of toxicological concern (TTC).

Leafy vegetables exhibited the highest concentration of organic pollutants – pharmaceuticals and personal care products as well as industrial chemicals, thus the highest human exposure to the wastewater-born pollutants was for population subgroups consuming high amounts of leafy vegetables, such as vegetarians and vegans. For the extreme exposure scenario (calculated as maximum contaminant concentration times the 95th percentile consumption), the anticonvulsant drugs Lamisil (lamotrigine), Tegretol (carbamazepine), and a therapeutically active metabolite of Tegretol exhibited the highest human exposure levels of 29, 27, and 19 micrograms per person per day, respectively. For the general population and using an average exposure scenario, the above-mentioned anticonvulsant pharmaceuticals exhibited exposure levels below the ADI and TTC thresholds. However, for the extreme scenario, the exposure level of Tegretol was higher than its ADI level. In addition, the maximum exposure levels of Lamisil and the therapeutically active metabolite of Tegretol were higher than the TTC level for genotoxic compounds.

#### THE ENVIRONMENTAL BEHAVIOR AND IMPACT OF MICROPLASTICS AT THE SOIL WATER INTERFACE

Z. GUAN

Institute of Mountain Hazards and Environment, CAS, Chengdu, CHINA

Due to the persistence and potential biological toxicity of microplastics (MPs), MPs pollution has become a global environmental issue. The interaction between soil colloids and typical nano MPs (polystyrene, PS) were investigated as terrestrial ecosystems was the largest repository of MPs and the environmental behavior of MPs at the soil water interface was an important pathway for the input of MPs pollution from land to the ocean. It was found that, MPs aggregated onto different soil colloids to formed "microplastic-soil colloidal polymers" and the presence of soil colloids had an inhibitory effect on the migration of MPs. It mainly attributed to the steric hindrance of soil colloids and their adhesive effect. On the contrary, the presence of MPs promoted the migration of four soil colloids mainly because the hydrophobic-to-hydrophilic transition of soil colloid particles surface occurred in water. Three types of aged MPs with the same concentration were used to investigated their influences on the rhizosphere soil bacterial communities in the meantime. The surface roughness, porosity, the oxygen-containing functional groups of aged MPs were increased, the surface contact angle decreased simultaneously. Compared to the unaged MPs, the diversities of microbiota in three different rhizosphere soils were variously increased, but the relative abundance of some various phyla and genera related to pollution degradation were inconsistent with different soil, indicating that the aged MPs in different soil may have miscellaneous biodegradation pathways.

Microplastic pollution was first reported in the oceans, and the research focus shifted to terrestrial and freshwater systems only recently. Because most of the microplastics are produced on land, studying terrestrial systems is crucial to understand the microplastics transport. While agricultural soils have received relatively large attention recently, little is known about floodplain soil at the interface between terrestrial and freshwater systems. Rivers play a crucial role in transporting microplastics into the ocean, but they can also act as potential sinks due to microplastic deposition in riverbed sediments and adjacent floodplains. Floods, in particular, can (re)mobilize and relocate microplastics in floodplains based on their topography. However, there is limited knowledge about the input pathways, spatial distribution, and fate of microplastics in floodplains. To address this, we sampled soil at varying depths along three transects in Rhine floodplains and analyzed microplastic abundance and mass concentrations using FTIR and pyrolysis GC/MS. A hydrodynamic flood model was set up to study the influence of flood frequency on microplastic distribution. Results showed a consistent pattern of microplastic distribution, with the highest abundance and concentration in topographical depressions where floodwater is retained and thus more particles are deposited. The study emphasizes the relationship between microplastic distribution in floodplains and the combination of flood frequency and local topography, highlighting the need for further research on the long-term fate of microplastics in floodplain soils.

Hydrophobic organic compounds (HOCs), such as halogenated aromatic hydrocarbons, can be very persistent in the environment and lead to adverse effects on humans and other biota. Sorption processes are highly relevant for the assessment of their environmental fate and risk. In this context, especially the interactions between HOCs and organic matter are intensively studied. However, significant HOC adsorption can also occur on clay mineral (CM) phases [1].

For the mechanistic elucidation of HOC–CM interactions, laboratory experiments have been combined with molecular modeling, both for various HOC–CM systems [1, 2, 3].

This work presents results from HOC–CM interaction studies with five halogenated benzenes (hydrophobicity range of log KOW 2.6–6.5) as HOC representatives. Twelve pure phyllosilicate CMs and 20 smectite-rich bentonites were used as mineral phases in laboratory adsorption experiments. Molecular modeling of interactions was performed at the density functional theory (DFT) level for montmorillonite models of varying mineral structure and with explicit solvation.

Results showed a strong mutual influence of HOC and CM properties on the extent of adsorption. The hydrophobicity of the HOCs played a relevant role in the extent of adsorption, but to a lesser extent than the mineral properties.

In particular, the results: (i) indicate the general influence of CMs on HOC adsorption as well as its wide variation (solid-liquid adsorption coefficients varied over several orders of magnitude, log K<sub>d</sub> 0.9–4.5); (ii) provide mechanistic understanding of the influence of CM layer charge, exchangeable cations, particle size, and pore size distribution on adsorption; and (iii) elucidate the hydration state as critical for adsorption energies and the nature of interaction processes.

Overall, the results suggest a strong influence of specific HOC–CM interactions on the environmental distribution behavior of HOCs with potential relevance for their fate and transport in the environment, e.g. for long-term source/sink phenomena in soils and sediments.

ENHANCED SORPTION OF PERFLUOROOCTANE SULFONATE (PFOS) BY OPTIMIZED MODIFIED LAYERED DOUBLE HYDROXIDES: PERFORMANCE AND MECHANISMS

C. WEI, X. SONG, Y. ZHANG

INSTITUTE OF SOIL SCIENCE, CHINESE ACADEMY OF SCIENCES, NANJING, CHINA

The detrimental effects caused by per- or polyfluoroalkyl substances (PFAS) in the aquatic environment have garnered significant attention. Sorption is a cost-effective and environmentally friendly technique for remediating PFAS. Batch sorption experiments were conducted to evaluate the removal of perfluorooctane sulfonate (PFOS) by layered double hydroxides (LDHs) and modified LDHs. We investigated the behavior and mechanisms of three types of LDHs for PFOS. Batch experiments showed a rapid sorption process, reaching equilibrium within 10-60 min. The nitrate-LDHs exhibited the maximum uptake capacity of 865 mg/g. The exfoliating of LDHs into two-dimensional nanosheets can maximize the utilization of single sheets, improving the surface area, exposing the hydroxyl groups, and eliminating the steric hindrance for PFOS. We achieved thermal exfoliation of LDHs into LDHs nanosheets (namely LDHNSs) at low temperature. LDHNSs exhibited a sorption capacity for PFOS of 1502mg/g, which is 82% higher than that of LDHs. Structural characterization results demonstrated that LDHNSs provides more sorption sites for PFOS, resulting in rapid and high-capacity removal of PFOS through electrostatic interaction, ion exchange and hydrogen bonding. LDHNSs showed superior regeneration ability in five regeneration cycles compared to LDHs. Additionally, LDHNSs maintain superior removal performance of PFAS in diverse water matrices. The sorption performance can be further enhanced by combining expanded graphite (EG) with LDHNSs to increase the material's hydrophobicity, owing to the hydrophobic and hydrophilic characteristics of PFOS. The EG-LDHNSs exhibited higher efficiency, attributed to the synergy between the positively charged structural layers of LDHNSs, which facilitate strong electrostatic interactions, and the EG, which enhance hydrophobic interactions for PFOS sorption. Our findings contribute to the understanding of utilizing modified LDHs for the removal of PFAS compounds from groundwater.

<sup>3</sup> University of Chinese Academy of Sciences, Beijing, CHINA

Knowledge on runoff transport of manure-sourced antibiotics from farmland soil to aquatic environment is limited due to complexity of hydrological regime and pathways. This field study was conducted in the hilly area of Entisol in Jialing River basin of the upper reaches of the Yangtze River, southwest China. The study monitored natural rainfalls in 6° sloping orchard plots with free-range chickens, with an attempt to investigate the migration characteristics of typical antibiotics via surface runoff and leachate as well as the impact of manure presence. Results showed that rainstorms continuously carried away antibiotics in surface runoff and all target antibiotics including those with high affinities to soil were detected at the beginning of runoff production. Concentration of antibiotics was found to respond strongly to the instantaneous rainfall intensity, showing consistent fluctuations during rainfalls. Leachate collected at 50 cm depth responded ca.15 min late. Concentrations of sulfonamides and florfenicol were two orders of magnitude higher than that of tetracyclines and fluoroquinolones, while the latter mainly occurred in sediment particles. Compared to the control without raising chickens, antibiotics migration was considerably increased with the increased runoff production due to soil surface changes caused by chicken activities. Additionally, dynamics of antibiotic concentration significantly correlated with variations of chicken manure-derived colloids, indicating colloids-facilitated migration of antibiotics. Based on flow rate, the calculated flux of sulfonamides ranged from 0.03 to 1.51 microgram/(m<sup>2</sup>·h) for surface runoff and from 0.45 to 4.52 microgram/(m<sup>2</sup>·h) for leachate, respectively, indicating leachate is an important pathway for contaminant transport in the studied area where the soil is rich in preferential flow of macropores.

THE EMERGING THREAT OF DIFFERENT MPS FOR PLANT-SOIL SYSTEMS AND THEIR FATE IN AGRICULTURAL SOILS

H. GUI

Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, CHINA

Plastics accumulating in the environment, especially microplastics (MPs, defined as particles <5 mm), can lead to a range of problems and potential loss of ecosystem services. Current research has demonstrated the significant impact of MPs on aquatic systems, but little remains known about their effects on terrestrial environments and their fate in soil, especially within agroecosystems. Therefore, we conducted a microcosm study to investigate how different types of MPs, including bio-degradable MPs, influence plant-microbe-soil interactions in agroecosystems. Combining <sup>14</sup>C-labeling, zymography with substrate-induced growth respiration, and pyrosequencing techniques, we found that the addition of MPs in the soil can significantly alter a range of key soil biogeochemical processes by changing soil properties, forming specific microbial hotspots, exerting multiple effects on microbial activities and functions. We also introduced the positive influences of nano-Fe on the plant-soil system in MP-polluted soil and establish a method to alleviate the harmful effects of MP accumulation in soils. In addition, the fate of these microplastics in the soil remains unclear. We also isolated a polyurethane (PU)-degrading fungus from soils, and the fungus H14 was identified as *Fusarium solani*. The ability of *F. solani* H14 of degrading PU film and PUPB patches was confirmed via mass loss, scanning electron microscopy (SEM) and enzyme production ability. These studies can greatly enhance our understanding of the possible ways of alleviating MP pollutions in agricultural soil.

Animal antibiotic use contributes to antimicrobial resistance (AMR) in humans. Agricultural benefits of animal manure can be overshadowed by its role as a hotspot for antibiotic-resistant bacteria, their genes, and antibiotic residues. Of particular significance are fluoroquinolones, a class of antibiotics crucial for human health according to the World Health Organization. In Buenos Aires periurban agriculture, intensive poultry farming administers enrofloxacin, a fluoroquinolone, to the flocks via drinking water, and horticulture uses poultry litter as soil amendment. Fluoroquinolones' fate and AMR dissemination resulting from these practices remain poorly understood. Our research addresses this gap by tracing fluoroquinolones trajectory from poultry to lettuce in circular periurban agriculture. The presence of biomarkers for AMR is also included. Our biological model includes poultry litter as a source of fluoroquinolones, a soil with no prior history of poultry litter application and, *Lactuca sativa* (lettuce). Lettuce was chosen as a receptor of fluoroquinolones, representing a possible pathway for human exposure. Fresh poultry litter (FPL) was stored for six months before application as stored poultry litter (SPL) in the horticulture field experiment. The experiment included control (CRL) and manured (MPS) plots where lettuce (L) was cultivated till harvest. Enrofloxacin, was detected in FPL, while its primary metabolite, ciprofloxacin, was found in SPL. These antibiotics can represent a selective pressure favouring AMR in the environment. No fluoroquinolones were detected in MPS; however, L-MPS samples exhibited high ENR and CIP concentrations, providing evidence of fluoroquinolone bioaccumulation in plants. Despite soil quality improved in MPS plots compared to CTR, *sul1* gene abundance was 2.60 times higher reaching a relative abundance of -3.57 Log *sul1* per 16S rRNA. A smaller, but significant effect was registered for *intl1*. Poultry litter static storage is not an adequate treatment to stop transmission of antibiotics and AMR in circular agriculture. Stored poultry litter application to the soil contributes to soil pollution with this emergent contaminants and risk of human exposure to antibiotics through vegetables.

#### FATE OF PER- AND POLYFLUOROALKYL SUBSTANCES (PFAS) IN THE VADOSE ZONE FOLLOWING LAND-APPLICATION OF BIOSOLIDS: IMPACT OF SOIL PROPERTIES

L. PETER, L.S. LEE

Purdue University, Department of Agronomy, West Lafayette, USA

Beneficial reuse of biosolids as organic fertilizers can introduce PFAS into agricultural soils. This study evaluates the impact of soil properties on PFAS transport in a site that received biosolids in 2023 after an eight-year pause on land application. The study site is dominated by three soil series: a deep and slowly permeable Acredale silt loam, a deep and moderately permeable Bojac sandy loam and Tomotley loam. There are seven deep and shallow groundwater monitoring wells generally located along the borders of the site. Prior to resuming biosolid application, groundwater, soils, and runoff were collected to establish the extent of legacy PFAS contamination within the site. Samples were processed with appropriate clean up steps and PFAS concentrations determined using isotope dilution and uPLC Zeno Time of Flight mass spectrometry (uPLC/ZenoTOF). Thirteen PFAS of the 57 targeted were detected in all groundwater collections. Individual PFAS concentrations were higher in the lower depth wells (35 ft vs 50 ft). The four most detected PFAS were short chain perfluoroalkyl acids (PFAAs) including PFPeA (98%), PFHxA (82%) and PFHpA (88%). PFBS, PFHxS, PFOS, and PFOA were detected in >60% of all samples. Other PFAS detected in at least one well included PFBA, PFNA, FBSA, PFHpS and 6:2 FTS. Of all the PFAS, PFOA had the highest maximum concentration in groundwater (221.4 ng/l), followed by PFPeA (92.9 ng/L), PFHxA (78.2 ng/L) and PFBS (71.1 ng/L). In runoff, 20 PFAS were detected in samples collected pre-2023 biosolids application. Predominant PFAS in runoff were long chain PFAAs, with PFOS found at the highest average concentration (686 ng/L). Similarly, PFOS and other long chain PFAS were abundant in the topsoil across the different soil series. Extraction and analysis of post-application soil cores and groundwater samples are ongoing. Available PFAS data for pre- and post-2023 biosolids application will be coupled with hydrologic and soil factors towards identifying key factors impacting PFAS retention and transport in the vadose zone.

### 4. Soil health in achieving the Sustainable Development Goals 4.19 133576 - Soil N<sub>2</sub>O emissions: understanding the underlying mechanisms and assessing the impact of soil management strategies

#### THE EFFECT OF PLANTAIN (*PLANTAGO LANCEOLATA* L.) IN PASTURE SWARDS ON GASEOUS NITROGEN EMISSIONS FOLLOWING CATTLE URINE DEPOSITION

K. DING<sup>1</sup>, J. LUO<sup>1</sup>, B. WELTON<sup>1</sup>, C. DE KLEIN<sup>2</sup>

<sup>1</sup> AgResearch, Ruakura Research Centre, Hamilton, NEW ZEALAND

<sup>2</sup> AgResearch, Invermay Agricultural Centre, Dunedin, NEW ZEALAND

Plantain (*Plantago lanceolata* L.) has been shown to possess biological nitrification inhibiting (BNI) activity, which can reduce nitrous oxide (N<sub>2</sub>O) emissions from ruminant urine patches in pasture soil. However, plantain's effectiveness in mitigating emissions and the underlying mechanisms remain uncertain. In this lysimeter study, the <sup>15</sup>N flux method explored the link between various plantain proportions in pasture sward and gaseous nitrogen loss (N<sub>2</sub>O and dinitrogen (N<sub>2</sub>)) after dairy cow urine deposition at 660 kg N ha<sup>-1</sup> on two contrasting soil types (Allophanic and Gley). The findings suggest that plantain presence could reduce cumulative N<sub>2</sub>O emissions after urine deposition, but with no direct correlation between the nominal plantain sowing rate and its mitigation effectiveness. However, in the Allophanic soil, there was a reduction in cumulative N<sub>2</sub>O emissions with an increase in the proportion of plantain in the dry matter. There was no such correlation in the Gley soil, which suggests that soil type may play an important role in modulating the BNI effect on N<sub>2</sub>O emissions reduction. The heavy rainfall-induced high soil moisture during the experimental period resulted in 48-60% of the applied N being lost through N<sub>2</sub> emissions. Plantain presence increased total N<sub>2</sub> emissions in both soil types, possibly due to its BNI function, which would retain mineral N in the soil for an extended period, providing substrate for denitrifiers to produce N<sub>2</sub> when conditions favour complete denitrification. The increase in N<sub>2</sub> production with plantain presence was more pronounced in the Allophanic soil than in the Gley soil, which could potentially be attributed to deeper root distribution in the Allophanic soil, which could have further influenced soil denitrification at greater soil depths. However, further information on the impact of plantain on mineral N concentrations at greater depth is needed to better understand the observed variations in gaseous N emissions.

### 4. Soil health in achieving the Sustainable Development Goals 4.19 133576 - Soil N<sub>2</sub>O emissions: understanding the underlying mechanisms and assessing the impact of soil management strategies

#### GREENHOUSE GAS EMISSIONS FROM RICE PRODUCTION IN ARKANSAS

D. DELLA LUNGA, K. BRYE

University of Arkansas, Fayetteville, USA

In the last decade, mitigation practices to reduce greenhouse gas (GHG) emissions [i.e., methane (CH<sub>4</sub>), nitrous oxide (N<sub>2</sub>O), and carbon dioxide (CO<sub>2</sub>)] and global warming potential (GWP) in rice (*Oryza sativa*) production systems in the United States, specifically Arkansas, have been evaluated in field conditions and greenhouse settings. The series of research studies has been conducted using the vented, non-flow-through, non-steady-state, closed-chamber approach. Environmental and agronomic factors assessed in the studies included soil texture (silt loam and clay), crop rotation (rice-soybean and rice-rice), plant variety (pure line and hybrid), nitrogen (N) source (urea, poultry litter, and ammonium sulfate), water regime (delayed-flood, mid-season drainage, and furrow-irrigation), tillage (conventional tillage and no-tillage), slow-release N (Environmentally Smart N) and slow-release phosphorus (P) (struvite) fertilizers. Results indicated that, regardless of water regime, decreased tillage intensity and/or frequency will contribute to reduced CO<sub>2</sub> emissions. Results indicated that flood-irrigated rice production on clay compared to silt-loam soils, flood-irrigated rice production with a hybrid rice cultivar compared to pure lines, flood-irrigated rice-soybean compared to rice-rice rotation, flood-irrigated rice fertilized with inorganic nutrient sources compared to poultry litter, furrow-irrigation, and struvite material as P source in flooded and furrow-irrigated conditions will contribute to reduced CH<sub>4</sub> emissions. Results indicated that furrow-irrigated rice production with no-tillage, maintaining uniform soil moisture conditions or avoiding large and frequent soil moisture fluctuations in furrow-irrigated rice production, and the use of ESN as N source in furrow-irrigated conditions will contribute to reduced N<sub>2</sub>O emissions. Results suggested that furrow-irrigation compared to flooded conditions can reduce GWP. Agricultural decisions involving which soil or plant characteristics and management practices to use can often be adjusted to reduce a single GHG. However, it is more challenging to prescribe a course of action that will simultaneously reduce multiple GHGs. The current level of knowledge regarding GHG emissions from rice production practices needs to be continually updated and extended with scientifically evidence to conserve valuable soil, water, and air resources.

#### INCREASED NITROUS OXIDE EMISSIONS BY APPLICATION OF ORGANIC AMENDMENTS MAY LARGELY OFFSET THE CARBON BENEFITS

M. ZHOU

Institute of Mountain Hazards and Environment, Chinese Academy of Sciences, Chengdu, CHINA

Application of organic amendments increases soil carbon (C) sequestration but also affects the emission of the powerful greenhouse gas (GHG) nitrous oxide (N<sub>2</sub>O). However, effects of organic amendments on soil N<sub>2</sub>O emissions remain uncertain as long-term, multi-year measurements are mostly missing. Here we report on six years of measurements in a long-term field experiment in which we monitored N<sub>2</sub>O emissions from a subtropical wheat-maize rotation system under various managements. Soil N<sub>2</sub>O emissions were measured for a synthetic N fertilizer application treatment and three organic amendment application treatments. Soil N<sub>2</sub>O emissions showed great seasonal and inter-annual variations throughout the experimental period. The variations in soil N<sub>2</sub>O emissions across all treatments were correlated positively ( $P < 0.01$ ) with the temporal dynamics of soil temperature, soil water-filled pore space (WFPS) and soil NO<sub>3</sub><sup>-</sup> and dissolved organic carbon (DOC) concentrations. Throughout the experiment of six years, on average, application of organic amendments (either manure or crop residues) increased soil N<sub>2</sub>O emissions by over 30% compared with the application of synthetic N fertilizer only ( $P < 0.01$ ). This multi-year field study indicates that increased soil N<sub>2</sub>O emissions must be carefully considered when organic amendment practices are proposed to maximize the climate change mitigation potential of arable lands, particularly in subtropical climates.

Agricultural ecosystems are the largest source for soil nitrous oxide (N<sub>2</sub>O) emissions and understanding their spatial and temporal variability, particularly in agricultural ecosystems, is crucial for effective climate change mitigation measures, aligning with the targets established by the European Green Deal. Model simulations are an important tool to quantify N<sub>2</sub>O emissions over several years across land use, agricultural management, and climate at local, regional, or global scales. Here, we systematically evaluate simulated soil N<sub>2</sub>O emissions from six different regions in Austria representing main cultivation areas located in two different European biogeographical zones (alpine and continental) with the process-based ecosystem model LandscapeDNDC. We present region-specific daily and annual N<sub>2</sub>O emissions from arable and grassland soils over a ten-year period considering more than 70% of land area and crops grown in the study regions. To identify hot moments of N<sub>2</sub>O emissions, we defined a threshold of extreme N<sub>2</sub>O peaks as daily emissions by the equation: Peak > 3rd Quantile + 3 \* (3rd Quantile – 1st Quantile). The simulations show that specific crops and management activities have profound effects on daily N<sub>2</sub>O emissions. The share of N<sub>2</sub>O emitted as peak emissions ranges from 12% to 79% of total annual emissions. Overall, per hectare, the simulated mean annual N<sub>2</sub>O emissions are 69% lower from arable soils than from intensively managed grasslands, however, peak N<sub>2</sub>O emissions are higher and more frequent in the arable system. N<sub>2</sub>O peak events are mainly occurring between April and October from arable as well as grassland soils. N<sub>2</sub>O hotspots correlate to high soil organic carbon content or nitrogen fertilizer application rates, whereby the dominant controlling factors varied between regions and land use. The modelling results demonstrate potential environmental impacts and propose strategies for climate- and eco- friendly farming practices.

DIFFERENT NITROGEN FERTILIZER STRATEGIES TO REDUCE NITROUS OXIDE EMISSIONS ON A POTATO ROTATION IN A VOLCANIC ASH SOIL

M. ALFARO <sup>1</sup>, S. HUBE <sup>2</sup>, F. SALAZAR <sup>2</sup>, I. BELTRAN <sup>2</sup>, L. RAMIREZ <sup>2</sup>

<sup>1</sup> AgResearch Ltd, Ruakura Research Centre, HAMILTON, NEW ZEALAND

<sup>2</sup> Instituto de Investigaciones Agropecuarias, INIA Remehue, Osorno, CHILE

Southern Chile has the largest potato crop production in the country, with 50% of the national production, mainly under rainfed conditions. High nitrogen (N) fertilizer rates are applied, with risks of increasing soil N<sub>2</sub>O emissions. This study aimed to evaluate the effect of N rates and form of application on yield and N<sub>2</sub>O emissions of a potato-cover crop rotation. The experiment was carried out at INIA Remehue (40°52' S, 73°06' W), during 2016/17 and 2017/18, evaluating the application of 80, 150 and 300 kg N/ha (conventional N rate applied by farmers), applied 35% at planting (granular for all treatments) and 65% 45 días after planting (granular urea or foliar application, 2: 1 ratio of water: urea, for the 80 kg N/ha treatment). A control treatment with no N addition was also considered. In the first growing season, emissions varied between  $1.4 \pm 0.03$  and  $3.0 \pm 0.35$  kg N<sub>2</sub>O-N/ha, with higher emissions at the higher N rates applied ( $p < 0.05$ ), with no differences in yield production ( $p > 0.05$ ). In the second growing season a 43% less rainfall than an average year and 49% less than the previous season was registered, which reduced yields and emissions significantly, resulting in no differences between treatments ( $p > 0.05$ ). Emissions of N<sub>2</sub>O were related to NO<sub>3</sub> soil availability only during the first year of evaluation. On average, reducing N fertilization to 150 and 80 kg N/ha reduced N<sub>2</sub>O emissions up to 31% with no differences among these two treatments, and emission intensity up to 34% in the 80 kg N/ha treatment, without detrimental impact on crop yield. On rainfed systems, N fertilization can be significantly reduced in below average rainfall years. This would also reduce direct cost in fertilizer application, favouring the economic and environmental sustainability of potato producers in Southern Chile.

Figure 1. Dynamic of soil available N per treatment over the experimental period (0-20 cm) a) N-NH<sub>4</sub><sup>+</sup> [mg N-NH<sub>4</sub><sup>+</sup> kg<sup>-1</sup> dry soil], and b) N-NO<sub>3</sub><sup>-</sup> [mg N-NO<sub>3</sub><sup>-</sup> kg<sup>-1</sup> dry soil]. Bars indicate standard error of the mean (n=3).

Figure 2. Flux of N<sub>2</sub>O [mg N-N<sub>2</sub>O m<sup>-2</sup> d<sup>-1</sup>] per treatment during two cropping seasons. Bars indicate standard error of the mean (n=3). Black arrows indicate N fertilizer application to the potato crop (30% and 70% for the first and second arrow, respectively), grey arrows indicate the date of the oat cover crop seeding. No N fertilizer was applied to the cover crop.

#### SPATIAL AND TEMPORAL VARIABILITY OF SOIL GHG FLUXES OF URBAN GREENS

K. BUTTERBACH-BAHL, X. BAI, L.N. ANDREASSEN

Land-CRAFT, Agroecology, Aarhus University, Aarhus, DENMARK

Global urbanization has significantly affected land use, with former agricultural or forested land being used for human settlements and urban green spaces. How this urbanization may have affected the spatial and temporal patterns of soil greenhouse gas (GHG) fluxes, especially those of nitrous oxide (N<sub>2</sub>O), remains largely unexplored, although a recent study indicated that urbanization accelerates GHG fluxes from soils.

In this study, we investigated soil GHG fluxes at Aarhus University Park (AU Park), a public park located in a hilly landscape with different use intensities. Soil GHG fluxes were measured 2-3 times per week over a period of 7 months using a fast chamber approach at about 55 sampling points with different management, vegetation, and landscape position (uphill, slope, foothill, ponds). Specifically, we focused on the identification of GHG flux hot and cold spots, and thereby investigated the temporal persistence of such spatial emission patterns.

Our results show that GHG fluxes were highly variable over the observation period, but that major GHG flux hotspots, such as those near a pond, were hotspots at all observation times. In addition, we were able to relate the spatio-temporal variations in soil GHG fluxes to landscape parameters such as slope and exposition, and to soil parameters such as soil organic carbon concentration, pH, and texture.

Our measurements show that there are significant spatio-temporal variations in GHG fluxes in urban parks and that these variations are strongly influenced by environmental and landscape parameters. This observation may allow a better scaling of GHG fluxes of urban green spaces and thus a better assessment of how urbanization changes landscape fluxes.

The conversion of sugarcane straw into biochar and its application in soils has been proposed as a potential strategy to mitigate N<sub>2</sub>O emissions resulted from the application of nitrogen fertilizers and agroindustry residues in sugarcane fields. However, little is known about the impacts of biochar on soil greenhouse gas emissions in tropical conditions. This study assessed the effects of sugarcane straw-based biochar on soil N<sub>2</sub>O emissions and its interaction with functional genes associated with N<sub>2</sub>O production and consumption. This study also evaluated the impacts of biochar on soil carbon content and biomass production. The experiment was conducted in pots filled with 8 kg of dry soil and cultivated with sugarcane plants. The experiment was conducted in a randomized design with five treatments and five replicates. The evaluated treatments were: control (CTR), N fertilizer (NF), NF+15 Mg ha<sup>-1</sup> straw (NF+S); NF+5 Mg ha<sup>-1</sup> biochar (NF+B5); and NF+10 Mg ha<sup>-1</sup> biochar (NF+B10). Soil moisture was adjusted to 60% of water-holding capacity throughout the experimental period. Results showed that N fertilizer and straw significantly increased N<sub>2</sub>O emissions and high N<sub>2</sub>O emissions were observed in NF+S treatment. The application of biochar, on average, reduced N<sub>2</sub>O emissions by 73%. Soil N-NH<sub>4</sub><sup>+</sup> availability was reduced under NF+S but was greater in biochar treatments. The high N<sub>2</sub>O emission in NF+S was correlated the the abundance of AOB-amoA genes, suggesting that nitrification was the major N<sub>2</sub>O-producing pathway. Biochar effects on soil N<sub>2</sub>O emissions were not correlated with nitrification or denitrification genes. High soil carbon content was observed in biochar treatments. The NF+S treatment exhibited the highest yield-scaled N<sub>2</sub>O emission, indicating that more N<sub>2</sub>O was emitted per unit of sugarcane biomass produced. N<sub>2</sub>O-yield scaled emissions in biochar treatments were 62% lower than in NF+S. Thus, this study suggests that straw-based biochar can considered as a feasible strategy to reduce N<sub>2</sub>O emissions and increase soil carbon sequestration in tropical soils

Nitrous oxide (N<sub>2</sub>O) is one of the most important greenhouse gases (GHG). Even though 60% of all N<sub>2</sub>O emissions are released from natural ecosystems, most of the N<sub>2</sub>O flux research has focused on agricultural soils. Whilst these managed, nutrient-rich soils have been relatively well studied, little is known about N<sub>2</sub>O fluxes in nutrient-poor ecosystems (e.g., the Arctic).

It has been generally assumed that Arctic soils are not a significant source of N<sub>2</sub>O due to a very low nitrogen amount available in these soils. Only recently, several studies have reported significant N<sub>2</sub>O emissions from organic-rich Arctic soils; however, due to methodological challenges, extensive investigations on N<sub>2</sub>O fluxes in Arctic soils have been limited. As a result, the importance of N<sub>2</sub>O fluxes from this region to the global budget remains highly uncertain.

The recent advances in portable GHG analysers enabled us to quantify the N<sub>2</sub>O fluxes which might help to improve the understanding of N<sub>2</sub>O budget over Arctic regions. Here, extensive chamber-based field measurements using a portable N<sub>2</sub>O/CO<sub>2</sub> analyser were conducted in a thawing sub-Arctic permafrost peatland in northern Sweden (Stordalen Mire, Abisko) during different seasons; May (spring), July (peak growing season), and September (autumn) 2023. We measured carbon dioxide, methane and N<sub>2</sub>O concentrations on a dry-to-wet thawing gradient from palsa to bog to fen. Based on this data set, the N<sub>2</sub>O budget at different times of the year was analysed. In addition, the relationship between the N<sub>2</sub>O fluxes and environmental controls such as soil moisture, soil temperature, and photosynthetically active radiation (PAR) was investigated to better understand the processes underlying the N<sub>2</sub>O fluxes.

**THE IMPACT OF SOIL N<sub>2</sub>O EMISSION ON THE CLIMATE-SMART POTENTIAL OF CROPPING SYSTEMS: A STUDY USING CONTINUOUS EMISSION DATA WITH EDDY COVARIANCE.**

N RAJAN, D DAVIS

Texas A&M University, College Station, USA

Sorghum (*Sorghum bicolor*) holds a prominent position as a major biofuel feedstock crop in the United States, with 30 to 35% of grain production dedicated to ethanol manufacturing. However, accurate evaluation of the climate-smart potential of sorghum production systems is essential for estimating the carbon intensity associated with sorghum-based ethanol. For this purpose, an accurate assessment of soil greenhouse gas (GHG) emissions, including CO<sub>2</sub>, N<sub>2</sub>O, and CH<sub>4</sub>, is crucial to gauge the sustainability of sorghum as an ethanol feedstock. This study employs the eddy covariance method for continuous measurements of CO<sub>2</sub>, N<sub>2</sub>O, and CH<sub>4</sub> fluxes from a 90-acre sorghum field in the U.S. Southern Great Plains, managed with minimum tillage. Three years of comprehensive data reveal insights into the diurnal and temporal dynamics of GHG emissions. A significant correlation between diurnal N<sub>2</sub>O emissions and soil heat flux during peak emission periods in the growing season was identified. The incorporation of these findings into modeling enhances our comprehension of the GHG budget within sorghum cropping systems, contributing to a more nuanced understanding of its impact on the overall carbon intensity of sorghum ethanol production.

<sup>3</sup> Federal Research Centre for Forests, Vienna, AUSTRIA

Agriculture and other land use practices are major contributors to greenhouse gas emissions, especially for N<sub>2</sub>O and NH<sub>3</sub>. Nitrous oxide (N<sub>2</sub>O) is a highly potent greenhouse gas and ammonia (NH<sub>3</sub>) can re-react with soil and forms N<sub>2</sub>O or can cause other environmental issues in the surrounding. Biochar is known for its carbon sequestration potential due to its high proportion of recalcitrant organic compounds, however, biochar can also positively influence soil properties like water holding capacity, nutrient leaching and mitigation of nitrous oxide emissions and ammonia volatilisation. However, these effects depend on pedoclimatic conditions, the properties of the applied biochar, and other agricultural practises. Therefore, it is necessary to expand the knowledge of these effects, especially under field conditions, to generate valid estimates on biochar's mitigation potential for N<sub>2</sub>O and NH<sub>3</sub> emissions. A good and extensive data basis is essential for recommendations and a large-scale application in agriculture. In a two-year field experiment in Grabenegg (Lower Austria) we cultivated silage maize (*Zea mays*) in 2022 and spring wheat (*Triticum aestivum*) in 2023 with different organic (external organic matter, EOM) and inorganic (NPK) fertilisers. For the biochar treatments we applied 7 t/ha hardwood biochar additionally. The original soil was loamy, low in organic carbon and slightly acidic. We found substantial reductions with 36% (NPK) and 53% (compost) for N<sub>2</sub>O and 56% (NPK) and 40% (compost) for NH<sub>3</sub> emissions. There are several factors discussed in literature how biochar mitigates N<sub>2</sub>O and NH<sub>3</sub> emissions. We suggest that the immobilisation effect of biochar on NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> (which was observed in the soil) and possibly an increased dinitrogen monoxide reductase activity are responsible for this reduction. Our data support that biochar can be a suitable amendment for highly productive agroecosystems where high amounts of fertiliser are needed and often applied at one timepoint. Still, further investigations on the long-term effect on emission mitigation of biochar and the mechanisms behind are necessary.

The application of organic matter (OM) inputs to agricultural soils can increase soil carbon storage but may also lead to an increase in non-CO<sub>2</sub> greenhouse gas emissions. By using a weighted meta-analysis, we quantitatively synthesized the results of 53 field studies, which explore the effects of adding different OM inputs (crop residues, green manure, livestock manure, slurry, digestate, compost or biochar) to soil on N<sub>2</sub>O emissions in 15 European countries. Diverse arable crops, mainly cereals, were cultivated in monoculture or in crop rotations on mineral soils. Cumulative N<sub>2</sub>O emissions were monitored during periods from 30 to 1070 days in field experiments, which received OM inputs, alone or in combination with mineral N fertilizers, while mineral N fertilizers served as a control.

The overall effect of OM inputs on N<sub>2</sub>O emissions had a slight tendency to reduce emissions by 10%, and this effect became more pronounced with increasing carbon-to-nitrogen ratio of the OM inputs. Compost and biochar significantly reduced N<sub>2</sub>O emissions by 25% and 33%, respectively. However, the mitigation effect of biochar and compost declined with increasing soil pH or sand content. In addition, climate was an important moderator governing the N<sub>2</sub>O emission reduction, with a smaller effect observed under warmer or drier climatic conditions.

The effect of other OM inputs, such as green manure, crop residues, livestock manure, slurry and digestate on N<sub>2</sub>O emissions varied from -18% to +15% compared to mineral N fertilizers, but their effects were not statistically significant. Our meta-analysis also showed that the co-application of green manure, livestock manure, slurry and digestate with mineral N fertilizers increased N<sub>2</sub>O emissions by 30% compared to the use only mineral N fertilizers. However, substitution of mineral N fertilizers with organic fertilizers tended to reduce N<sub>2</sub>O emissions by 16%.

Our meta-analysis recommends establishing experiments, particularly, with livestock manure, green manure, slurry and digestate, which currently show either highly variable impact on N<sub>2</sub>O emissions or have a scarce number of studies.

### 4. Soil health in achieving the Sustainable Development Goals 4.19 133576 - Soil N<sub>2</sub>O emissions: understanding the underlying mechanisms and assessing the impact of soil management strategies

#### QUANTIFICATION AND PARTITIONING OF THE CONTRIBUTION OF ABIOTIC AND BIOTIC PROCESSES TO SOIL N-OXIDES EMISSIONS IN THE DEAD SEA VALLEY, ISRAEL

I. GELFAND, I. YAGLE

Ben Gurion University of the Negev, Beer Sheva, ISRAEL

Wetting of dry soil after prolonged drought triggers emissions of N-oxides (nitric oxide; NO and nitrous oxide; N<sub>2</sub>O) which may contribute disproportionately to annual soil N-oxides emissions in drylands. During the wetting, microbial processes were shown to be the major sources of soil N-oxides emissions. Abiotic reactions, however, may also contribute to the production of N-oxides in soils. The contribution of abiotic reactions despite potential importance is not well quantified. To quantify and partition the contribution of abiotic and biotic processes to post-wetting N-oxides emissions in drylands, we measured soil NO and N<sub>2</sub>O production in a laboratory with live and gamma-irradiated soils collected under canopies of dominant local (*Acacia tortilis*) and invasive (*Prosopis juliflora*) trees, as well as from bare soils outside the canopy cover.

We found that gamma-irradiated soils under *A. tortilis* canopies after eight hours' incubation, emitted ~10 times less NO (~5 ng N g<sup>-1</sup>) and ~4 times less N<sub>2</sub>O (~10 µg N g<sup>-1</sup>) compared to the live soils. While gamma irradiated soils under *P. juliflora* canopies emitted ~2 times less NO (~7 ng N g<sup>-1</sup>) and similar N<sub>2</sub>O (~7 µg N g<sup>-1</sup>) compared to the live soils, and in the soil from the bare area, ~9 times less NO (~5 ng N g<sup>-1</sup>) and similar N<sub>2</sub>O (~10 µg N g<sup>-1</sup>). Our findings suggest that both biotic and abiotic pathways contribute to N-oxides production following dry soil wetting, however, the relative contribution is dependent on the landscape position and affected by plant presence and species. In soil beneath *A. tortilis* abiotic processes contributed 10% to soil NO and 25% to N<sub>2</sub>O production. In soils soil under *P. juliflora* abiotic processes contributed 50% to NO and 100% to N<sub>2</sub>O production. In bare soils abiotic processes contributed 10% and 75%, for NO and N<sub>2</sub>O production, respectively.

<sup>4</sup> Department of Soil & Environment, Swedish University of Agricultural Sciences, Uppsala, SWEDEN

The Amazon is a global tipping element, with the potential to affect not only the global climate system but also the entire social-ecological system of Earth. Some of the human-induced myriads of environmental problems include forest conversion and climate change. Local stakeholders and researchers have identified droughts as one of the most urgent concerns: dry seasons have become longer and more intense, negatively affecting regional water budgets. Water scarcity is by far more critical in humid environments which are not adapted to these conditions at all. In the Amazon forest, the high soil microbial biodiversity serves as a safety net, providing functional redundancy to support the ecosystem in the face of stressors such as floods, fires, or intense droughts. The question is whether the functional biodiversity of the microbial heroes is lost due to forest conversion and if so, at what point in time, as well as if they return with natural regrowth as secondary forests. Greenhouse gas fluxes have proven to be potential indicators for early warning before crossing ecological tipping points in pasture's soils and therefore were used in this study to explore the effects of forest conversion on functional biodiversity within the N-cycle. In a field experiment in the Amazon, rainout shelters were installed on an aboveground biodiversity gradient ranging from primary and secondary forests to pastures and abandoned pastures. In sites, where all four aboveground biodiversity levels were in close proximity, field N<sub>2</sub>O measurements and soil sampling were conducted. In future, also functional gene-based amplicon sequencing is aimed. This study elucidates the intricate connections amongst forest conversion and N<sub>2</sub>O emissions in Amazon soils, and will underscore the critical need to comprehend the sources of N<sub>2</sub>O emissions within natural tropical ecosystems. In the quest to avoid crossing a tipping point, it is crucial to identify and understand pivotal system thresholds at an early stage to improve early warning identification tools and monitoring strategies.

Nitrous oxide (N<sub>2</sub>O) is one of the main problematic greenhouse gases (GHG). Between 2007 and 2016, 43% of the global N<sub>2</sub>O emissions were anthropogenic and half came from agriculture. Complex redox systems and multiple drivers effects challenge predicting N<sub>2</sub>O emissions. For example, crop residue removal has been shown to have either positive, negative or neutral effects on N<sub>2</sub>O emissions. Although meta-analysis show that crop residue return tends to increase N<sub>2</sub>O emissions in temperate climates, they also indicate that this trend is dependent on soil properties or other management practices. Regarding how crop residue influence N<sub>2</sub>O emissions, recent studies stress the major influence of residue quality. Despite numerous existing work, how crop residue globally influence cumulated emissions, with a GHG perspective remains difficult to evaluate due to the short duration of most studies. We hypothesized that using the whole time scale of a long term experiment covering a wide range of practices would allow to unravel the relative weight of crop residue management on N<sub>2</sub>O emissions. We compiled 1-site-10-years-8-cropping-systems experimental data and defined joint restitution cycles (109 days to 646 days) for which both cumulative emissions and key driving variables, including measures of crop residue return and quality, were defined. The analysis of the 158 restitution cycles indicated that nitrogen fertilizer rate and length of the period were the main variables explaining N<sub>2</sub>O emissions while the C:N ratio of residue was the main driver of crop residue influence, although that influence remains limited. The weight of crop residue influence was inversely proportional to the period length, supporting the importance of considering the timescale of measurements to evaluate how crop residue influence GHG emissions.

#### THE SOMMIT WEB DASHBOARD FOR EVALUATING SUSTAINABLE AGRICULTURAL MANAGEMENT STRATEGIES TO REDUCE NITROUS OXIDE EMISSIONS

G. MONGIANO <sup>1</sup>, R. CALONE <sup>2</sup>, A. FIORE <sup>3</sup>, A. LAGOMARSINO <sup>4</sup>, S. BREGAGLIO <sup>2</sup>

<sup>1</sup> Council for Agricultural Research and Economics, Research Centre for Plant Protection and Certification, Vercelli, ITALY

<sup>2</sup> Council for Agricultural Research and Economics, Research Centre for Agriculture and Environment, Bologna, ITALY

<sup>3</sup> Italian Institute for Environmental Protection and Research, Rome, ITALY

<sup>4</sup> Council for Agricultural Research and Economics, Research Centre for Agriculture and Environment, Florence, ITALY

The atmospheric concentration of nitrous oxide (N<sub>2</sub>O) has escalated from about 270 parts per billion (ppb) in the pre-industrial era to 336 ppb in 2022, primarily due to agricultural activities, which account for over 60% of anthropogenic N<sub>2</sub>O emissions. These emissions are significantly influenced by agricultural practices like fertilizer application, soil tillage, irrigation, harvesting, and managing crop residues, all of which impact the nitrogen cycle. Optimizing agricultural practices to lower N<sub>2</sub>O emissions while also considering their impact on other greenhouse gases and crop yields is a complex challenge.

The SOMMIT project, supported by the European Joint Programme for Soil, has developed the SOMMIT index (Si), a fuzzy logic-based trade-off analysis system. This tool is designed to assess alternative farming strategies quantitatively, examining the trade-offs between reducing N<sub>2</sub>O emissions and potential adverse impacts on soil carbon sequestration, crop yield, and nitrate leaching. The SOMMIT index has been applied to an extended dataset comprising around 2 million agronomic case scenarios (CS) from Italy, where multiple combinations of crops, farming practices, and pedoclimatic conditions are tested.

The analytical methodology has been implemented in a user-friendly, web-based dashboard, enabling access to this extensive CS dataset and facilitating the exploration of the Si values. The interface features a 3D scatterplot visualization based on a Multiple Factor Analysis, where each dimension is correlated with the CS's environmental, management, and trade-off components. CS are represented as points. Greater distance between points indicates greater differences in the agronomic CS, and their colours represent the Si ratings, with darker colours indicating lower Si values (worst CS) and lighter ones higher Si values (best CS). Hovering over a point reveals CS details, including N<sub>2</sub>O emissions, soil organic carbon changes, crop yield, nitrate leaching, and the Si.

This visualization tool is especially valuable for non-experts, simplifying complex data into an accessible and easy to interpret format. It assists in comparing and identifying optimal agronomic strategies, promoting informed decision-making in sustainable agriculture.

<sup>3</sup> Agriculture and Agri-Food Canada, Quebec Research and Development Centre,, Quebec city, CANADA

Agricultural organic soils are an economically important non-renewable resource with a vital role in Canadian vegetable production, however, these soils are highly susceptible to wind erosion and microbial decomposition. Conserving these soils is essential for food security as well as protecting the livelihoods of the landowners and their employees. Applying plant residues as mulches has been proposed to reduce soil erosion, however, these can change soil physicochemical environment to stimulate microbial activity and increase nitrous oxide (N<sub>2</sub>O) emissions. This project determined the effects of residue type on soil N<sub>2</sub>O emissions from an organic soil under lettuce production in south-western Québec (Canada), and evaluate some of the factors driving changes in N<sub>2</sub>O flux. During a two-year experiment, N<sub>2</sub>O emissions from soil mulched with switchgrass (*Panicum virgatum*), miscanthus (*Miscanthus sinensis*), ash (*Fraxinus pennsylvanica*), larch (*Larix laricina*), or willow (*Salix*) residues were compared to those from the same soil with a cover crop residue (fall-seeded rye; *Secale cereale*), and the absence of mulch, under either conventional tillage (control) or under no-till. In both years, the willow mulch treatment exhibited the lowest cumulative N<sub>2</sub>O emissions, a rate similar to the control soil. Compared to the control, soil mulched with ash, larch or willow residues showed no significant difference in CO<sub>2</sub> or CH<sub>4</sub> emissions. Peaks in N<sub>2</sub>O fluxes consistently followed peaks in soil NO<sub>3</sub><sup>-</sup> concentrations. A roughly 5-fold decrease in soil NO<sub>3</sub><sup>-</sup> and N<sub>2</sub>O emissions from 2021 to 2022 was attributed to the incorporation of the plant residues remaining at the end of the season possibly increasing N immobilization by microbes. Soil bacterial and fungal community structure and quantification of genes involved in the nitrification-denitrification pathways were also analysed to determine their impacts on reduced soil NO<sub>3</sub><sup>-</sup> concentrations and N<sub>2</sub>O emission. We conclude that wood-based mulch does not significantly increase greenhouse gas emissions from an organic agricultural soil and offers a promising option for producers interested in preventing soil erosion without increasing greenhouse gas emissions.

#### HOT, HOTTER, HOT MOMENTS? THE IMPACT OF SOIL TEXTURE ON SIMULATED N<sub>2</sub>O EMISSIONS AMIDST CLIMATE CHANGE

L. HEY<sup>1</sup>, K. H.E. MEURER<sup>2</sup>, H. F. JUNGKUNST<sup>1</sup>

<sup>1</sup> RPTU Kaiserslautern Landau, Landau, GERMANY

<sup>2</sup> Swedish University of Agricultural Science - SLU, Uppsala, SWEDEN

The consensus in the scientific community is that N<sub>2</sub>O emissions are expected to increase with climate change. A warmer and wetter climate, characterized by prolonged dry spells and increasing intensities of precipitation, fosters the emergence of 'hot moments' – short term emission pulses considerably contributing to annual N<sub>2</sub>O emissions. Due to the inherent high spatiotemporal variability of N<sub>2</sub>O, these hot moments are difficult to predict and, therefore, challenging to model. The complexity of modelling is further compounded by the influence of soil texture. While climatic change plays a key role in the potential emergence of hot moments, soil texture determines the likelihood that aerobic or anaerobic conditions will prevail, affecting the fundamental mechanisms of N<sub>2</sub>O emissions.

In this study we aim to explore how different soil textures impact the simulation of N<sub>2</sub>O emissions, taking precipitation intensity and dry spells induced by future climate change into account. This calculation exercise is based on climate projections from the multi-model ensemble of the EURO-CORDEX initiative and the biogeochemical models CANDY, LDNDC, DNDC and DayCent. Given the differences in the algorithms of these biogeochemical models, which are crucial for N<sub>2</sub>O simulations, and the critical role of soil texture linked with climate change, we expect to reveal both strengths and shortcomings in depicting hot moments of N<sub>2</sub>O. We aim to identify where and how much improvement is needed to simulate N<sub>2</sub>O emissions associated with hot moments, climate change, and diverse soil textures. Specifically, our ultimate goal is to enhance the simulation capabilities of biogeochemical models and their ability to depict dry-wet cycle induced hot moments in the context of climate change with a possible reinforcing effect by soil texture.

Soil organic matter (SOM) is an essential factor for soil health and functionality assessment, as well as for climate regulation, through carbon sequestration and greenhouse gases emissions regulation. An accurate estimation and monitoring of the SOM content is crucial for sustainable land management and climate change mitigation strategies through the adoption of tailored carbon farming practices. In recent years, there has been a growing consciousness of the need to better understand the dynamics of SOM in time and space in relation to different agronomic practices.

In this context, this study aims to improve our understanding and get some insights about the relationship between SOM and the main farming systems adopted in Italy: conventional, organic and regenerative farming. The three farming systems were compared collecting a large dataset consisting of SOM values and environmental and farming information collected in 593 locations representative of the whole agricultural area of Po Valley in Italy. This large dataset was analyzed by a geospatial analysis using a geostatistical approach for modelling and understanding the SOM spatial variability over the different fields characterized by irregular shapes and different farming systems.

Clear evidences of the spatial correlation between SOM, farming systems and soil types were detected. More in detail, Cambisols and field managed according regenerative agriculture principles showed higher SOM contents as compared to other farming systems and soil types. Moreover the study demonstrated how the inclusion of fodder crops in the rotation and the use of no-tillage are two of the most effective practices for increasing and preserving SOM according.

Spatial information, such those provided in this study, could contribute to the delineation of tailored solutions for each EU Member State to guide future actions related to carbon farming, and offer crucial insights to support agriculture progress for enhancing soil fertility and health and fostering sustainable agricultural practices.

The world is facing unprecedented environmental and food security challenges. Agricultural production must be resilient and adapt to the changing climate to meet the growing demands for food and energy. Sustainable agricultural practices have been important in meeting this challenge and aims to increase crop yield and livestock productivity thereby increasing farm profitability while maintaining or enhancing soil, water resources and other ecosystem services. In this regard, conservation practices can provide multiple soil health, agricultural production, and environmental benefits. In addition, it can enhance the resilience of soil and cropping systems to climate variability and change induced risks while also mitigating climate change by reducing emissions and/or enhancing soil organic carbon sequestration. Here, we present the USDA ARS led Long-Term Agroecosystem Research (LTAR) Network research effort on several aspects of sustainability; review other published research results on sustainability and resilience, its impact on soil and crop system and the link with food security and ecosystem sustainability. We also evaluate the past achievements, future challenges and indicate research priorities.

##### CARBON STOCKS AND BIOCHAR PRODUCTION IN ABANDONED BAMBOO FOREST, JAPAN

M. ADACHI <sup>1</sup>, D. FORSTER <sup>1</sup>, K. TANAKA <sup>1</sup>, A.M. KISHIMOTO <sup>2</sup>, J. NISHIHIRO <sup>3</sup>

<sup>1</sup> Toho University, Faculty of Science, Funabashi, JAPAN

<sup>3</sup> National Institute for Environmental Studies, Center for Climate Change Adaptation, Tsukuba, JAPAN

Abandoned bamboo forests have expanded into timber forests and abandoned fields in Japan, leading to biodiversity degradation and increased risk of landslides. Moso bamboo (*Phyllostachys pubescens*) is faster growing than trees, and reproduces via an extensive underground rhizome network. Biochar is recognized as an effective method for long-term sequestration of photosynthetically fixed carbon, and may therefore be an effective use of bamboo biomass. The objectives of this study are 1) clarify the carbon stock of soil and biomass in abandoned bamboo forest and 2) estimation of the amount of biochar production by bamboo in the northern part of Japan.

The study was conducted at an abandoned bamboo forest in Eastern Japan. The site was dominated by a bamboo stand for at least 17 years judging from aerial photographs. Two adjacent study plots (10 m x 20 m) were established, with a slope angle of about 42.6 degrees. We investigated the living and dead culm density, the weight of downed culms (woody debris), and the amount of living biomass. Additionally, we calculated the biochar production rate from living and dead culms using a simple on-site carbonization method.

Total stem density of bamboo stand (both of living and dead) was estimated 13,600 culms ha<sup>-1</sup>. The standing biomass and fallen bamboo were estimated at about 243 and 373 t dry weight ha<sup>-1</sup>, respectively. Because bamboo has a high water content after cutting, it is usually left to dry for two to three months before being carbonized. Carbonization rate of living and fallen bamboo were about 12.8 and 15.9%, respectively, because high water content of culm decreased efficiency of carbonization. Therefore, biochar production by living and fallen bamboo was estimated about 31 and 72 t C ha<sup>-1</sup>. Next year we will research the decomposition rate of bamboo, and then plan to consider the carbon cycle including management and biochar production at regional scales.

Composting is a common practice to aerobically convert and recycle organic waste biomass from different origins into a new agronomic input. The use of on-farm compost has increased in recent years, providing an alternative to commercial compost. The use of biochar in composting operations has attracted interest due to the multiple potential benefits arising from such practice, including improved C/N ratio, faster composting operations, ameliorated quality of the composted material, reduction of emissions and higher nutrient retention.

This work presents the results of an open field experiment which investigated the effects of the application of co-composted biochar with manure (CB), compared with stabilized manure without biochar addition (MN), NPK-based inorganic fertilization (NPK) and control treatments (CK) (no fertilization or amendment) on spring barley growth and yield. Several soil chemical parameters were analyzed in soil to determine significant variations among treatments. Barley biomass was evaluated at the phenological stage of milky caryopsis ripening (May) and at the vitreous caryopsis stage (June). The growing season was characterized by low rainfall and prolonged dry spells. Significant effects have been observed on barley biomass and seed yield for co-composted biochar, compared to all other treatments, including NPK. Plants amended with CB showed the highest biomass value (Figure 1A) at harvest. Furthermore, the same statistical trend was observed for the grain yield parameter (Figure 1B). In detail, the grain yield of the plants cultivated with CB showed a significant increase of about 40% compared to CK, MN, and NPK treatments.

Moreover, co-composted biochar and manure (CB) proved to be a valid treatment to preserve the initial soil organic carbon (final TOC=23.3), providing a common C/N value for agricultural soil. These findings suggest that biochar can improve the agronomic efficiency of manure, providing a valid alternative to common on-farm handling of manure, and contributing to the offsetting of inorganic fertilizer demand in organic agriculture with low rainfall.

##### SIMULATION OF THE LONG-TERM EFFECT OF CARBON FARMING PRACTICES UNDER FUTURE CLIMATE

V ROMANENKOV, I KHUSNIEV, I ILICHEV, P KRASILNIKOV

Moscow State University, Moscow, RUSSIA

For 6 long-term field experiments with fertilizers located in the European Russia on retisols, podzols and chernozems, the observed and predicted dynamics of soil organic carbon stocks in the arable layer was studied for the contrasted treatments. RothC dynamic model was used to assess the impact of climate change until the end of the century on the ability to enhance carbon sequestration after modification of agricultural practices. The impact of such carbon farming practices as elimination of the fallow field; changes in crop rotation; rates of applied manure; replacing manure with alternative organic fertilizers and minimum tillage was simulated. For almost all the experiments studied, the forecast of soil OM dynamics under future climate makes it possible to achieve the goal of 4 ppm. The period until 2055-60 is more favorable for sequestration of C. For chernozems, the accumulation period is limited to 2040, after which it is possible to maintain previously accumulated C stocks until 2070-80, after which losses are expected to accelerate. In this period RCP4.5 climate scenario tends to be more favorable compared to the RCP8.5 when soil C stock is less than 30 Mg/ha, an additional accumulation of about 2 ppm is provided. The average C rate accumulation does not exceed 10‰, although for podzols it can be as high as 20‰. For SOC stocks more than 60 Mg/ha, no differences are observed between the two climate scenarios. The most promising carbon farming practices are correct rate of organic fertilizers as well as perennial grasses in crop rotation. The application of alternative sources of organic fertilizers made it possible to accumulate additional C, while the efficiency decreased in the series compost and peat mixtures > biochar > manure > green manure in equivalent C rates. Changing the manure rates and replacing manure with alternative organic fertilizers is considered as a short-term effect, manifested mainly in the accumulation of additional C stock, without changing the time of saturation.

##### INFLUENCE OF DIFFERENT AGRICULTURAL MANAGERMENTS ON SOIL ORGANIC MATTER DISTRIBUTION AND STABILITY IN TOPSOIL AND SUBSOIL

C. POESIO <sup>1</sup>, M. DE FEUDIS <sup>2</sup>, G. TOSTI <sup>1</sup>, F. TEI <sup>1</sup>, L. VITTORI ANTISARI <sup>2</sup>, A. AGNELLI <sup>1,3</sup>

<sup>3</sup> Research Institute on Terrestrial Ecosystems (IRET), National Research Council (CNR), Sesto Fiorentino, Firenze, ITALY

The aim of the study was to investigate how agricultural management affected the functional SOC pools in topsoil and subsoil of a Typic Haplustept developed from fluvial-lacustrine sediments in Umbria region, Italy. The research was conducted in a mid-term trial [11 years - wheat-tomato rotation (first 4 years) and wheat-maize rotation (last 7 years)] where three managements were implemented: CONV - integrated management with no cover crop and conventional tillage, ORG - organic management with cover crop and conventional tillage, NOT - integrated management with cover crop and no-till. Within each plot, soils were sampled by horizons, and the samples were fractionated obtaining the following SOC fractions: labile (WEOM and POM), stable (aggregates of size 2-0.05 mm, SSA, and < 0.05 mm, SCA) and resistant to NaClO oxidation. Although TOC content did not change among managements, except for NOT topsoil (0-20 cm), the ORG and NOT soils showed greater proportion of OC associated with SSA throughout the soil depths. Lower phenols concentration was also found in the upper layer of ORG and NOT, that was attributed to the incorporation of lignin-poor material (legume cover crops). Regarding the  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  determined in the different fractions, whereas  $\delta^{13}\text{C}$  showed a wide variability due to the presence of C3 and C4 plants in the rotation, the high  $\delta^{15}\text{N}$  in ORG and NOT suggested the occurrence of intense mineralization, likely due to a priming effect promoted by the green manuring with legume cover crops. This hypothesis would be supported also by the larger C-CO<sub>2</sub>/C<sub>mic</sub> and C-CO<sub>2</sub>/C<sub>labile</sub> ratios in the subsoil of ORG and NOT compared to that of CONV. Considering the whole profile, the three managements had similar organic C stocks. For NOT management the highest C stock was in the topsoil, mostly as labile C and in the SSA. For CONV and ORG managements the highest C stock occur in the 20-40 cm layer, mostly in the stable pool.

To address the adverse effects of agriculture on climate change, it is imperative to adopt soil management practices that minimize greenhouse gas (GHG) emissions. A promising approach involves incorporating biochar into fertilizers to enhance carbon sequestration in the soil while simultaneously reducing N<sub>2</sub>O emission. Although previous studies have explored the impact of biochar on reducing soil nitrous oxide (N<sub>2</sub>O) emissions, the specific effects of blending biochar into manure-based fertilizer remained understudied. In this field experiment, we compared soil N<sub>2</sub>O emissions during lettuce cultivation across six treatments: chemical pelleted fertilizer (CF), cattle-manure-based pelleted fertilizer (CT), cattle-manure-based agglomerated fertilizers blended with biochar made from three different feedstocks (rice husk (RB), poultry manure (PB), and coffee grounds (CB)), and no fertilizer (NF). Cumulative N<sub>2</sub>O emissions were significantly lower in CT and biochar-blended fertilizer (RB, PB and CB) treatments compared to CF treatment. Biochar-blended fertilizers, particularly those incorporating rice husk biochar, tended to reduce N<sub>2</sub>O emissions immediately after fertilizer application when compared to CT. Soil inorganic nitrogen and lettuce yield did not show significant differences among the treatments, except in the case of no fertilizer control (NF). This suggests that the reduction in N<sub>2</sub>O emissions with all fertilizer treatments may not be attributed to a decrease in inorganic nitrogen concentration but rather to alterations in the activities of nitrifying and denitrifying bacteria responsible for N<sub>2</sub>O production from inorganic nitrogen. Our findings support the use of cattle-manure-based agglomerated fertilizers blended with biochar as an effective approach to mitigating N<sub>2</sub>O emissions from agricultural soils, concurrently enhancing soil carbon through biochar incorporation.

This work was supported by the MAFF Commissioned Project study on "Enhancing Carbon Sequestration Capacity in Agricultural Soils through Biochar Development" (Grant Number JP J008722).

##### APPLICATION OF ORGANIC AMENDMENTS IN INFERTILE SANDY SOILS DOES NOT ALWAYS FOLLOW “MORE IS BETTER”: CARBON SEQUESTRATION AND ECONOMIC EVALUATION PERSPECTIVES

J. WANG, C. XU, S. YANG, C. LI, J. ZHANG, Y. AI, Y. ZHANG

National Agricultural Experimental Station for Agricultural Environment, Liuhe /Institute of Agricultural Resources and, Nanjing, CHINA

A thorough understanding of the agricultural, ecological, and economic benefits of organic amendment (OA) application in infertile soils is crucial for facilitating agricultural sustainability. We conducted a three-year field study to evaluate the effects of OA application on fractions and sequestration rates of soil organic carbon (SOC), crop yield, and net ecosystem economic benefit (NEEB) in a typical infertile sandy soil of the ancient Yellow River alluvial plain. In addition to CK (non-OA application), two types of OAs, i.e., manure-based organic fertilizer (M) and straw-based mushroom residue (S) were each applied at 12, 24, and 36 Mg ha<sup>-1</sup> yr<sup>-1</sup>. Two scenarios of OA application practices, conventional manual OA application (AMA) and mechanical OA application (AME), were considered in the economic evaluation. An increase of 1 g kg<sup>-1</sup> SOC content could improve the crop yield by 2.25 Mg ha<sup>-1</sup> yr<sup>-1</sup>. Compared with CK, OAs application increased SOC content by 5.94%-35.4%, easily oxidizable SOC by 17.6%-40.9%, light fraction by 24.3%-102%, and heavy fraction by 75%-137%. However, SOC sequestration efficiency of the OAs tended to decrease under high rates of OA application. S was observed to have more potential in sequestering SOC among the treatments. Owing to SOC sequestration, OA application reduced the global warming potential cost by 28%-119% compared with the CK. Nevertheless, the benefits of OA application on yield and SOC sequestration were substantially covered by the increased material and labor costs when evaluating the NEEB. Compared with AMA, AME could save 10%-27% of agricultural costs. AME of B at a rate of 24 Mg ha<sup>-1</sup> yr<sup>-1</sup> achieved the highest NEEB. This study implied that the strategy of “the right OA, right application rate, and right spreading practice for the right soil” should be proposed to achieve a sustainable solution for promoting crop productivity, enhancing SOC sequestration, and ensuring farmer income in infertile farming regions.

##### THE EFFECTS AND PERCEPTIONS OF SPONTANEOUS COVER CROPS ON SOIL QUALITY IN MEDITERRANEAN ORCHARDS: A CASE STUDY CONDUCTED IN SOUTH-EAST SPAIN

N. TABAK<sup>1,2</sup>, A. MORUGÁN CORONADO<sup>1</sup>, E. SAMPER PÉREZ<sup>1</sup>, E. HUERTA LWANGA<sup>2</sup>, R. ZORNOZA BELMONTE<sup>1</sup>, M.D. GÓMEZ LÓPEZ<sup>1</sup>

<sup>2</sup> Wageningen University & Research, WAGENINGEN, THE NETHERLANDS

Intensification of farming systems normally leads to soil degradation, which nowadays poses a severe risk in sustainable food production. To mitigate soil degradation, sustainable land management practices (SLM) are implemented. A SLM practice that has been getting much attention lately, is the adoption of cover crops. This is also the case in orchards in South-East Spain, where soil degradation is severe, and the farming conditions are aggravated due to the semiarid climate. This study examined the perceptions and effects of spontaneous cover crops on soil quality in Mediterranean orchards (olive and fruit). Twelve farms in South-East Spain, six using cover crops (CC) and six not using cover crops (TR), were analysed for aggregate stability, water holding capacity, unsaturated hydraulic conductivity, dry bulk density, soil moisture, pH, electrical conductivity, cation exchange capacity, organic carbon, total carbon and nitrogen and bioavailable phosphorus. Additionally, regional farm advisors were interviewed, and farmers surveyed regarding (spontaneous) cover crop implementation. The results indicated that solely total carbon was significantly higher in CC-treated soils ( $P=7.02E-5$ ). However, unsaturated hydraulic conductivity and available water holding capacity were significantly lower ( $P$ -values  $2.45E-4$  and  $1.02E-2$ , respectively). Other soil parameters showed no significant differences. The principal component analysis suggested minimal variation between CC and TR treatments, indicating limited impact of spontaneous cover crops on soil quality in these orchards. Analysis of the perceptions of farm advisors and farmers highlighted the difficulty of adopting cover crops in the study area: all stakeholders indicated that the implementation of (spontaneous) cover crops is, to some extent, inconceivable. Stakeholders fear that cover crops limit water availability for the main cultivating crop. Consequently, the endorsement of implementing spontaneous cover crops is insufficient. These results highlight the urgent need for further research of (other) conservation practices to successfully mitigate soil degradation in Mediterranean orchards.

Healthy soils are key to ensure sustainable food production. However, many agricultural soils, particularly in the tropics, are highly degraded and a major limiting factor for crop production. Improved crop and soil management practices have the potential to increase crop yields and soil carbon and nutrient storage, but pedoclimatic conditions are constraining factors that need to be considered when recommending crops and management. In this study, we sampled 427 fields across 80 sites along eight elevational transects in the southwest of Ethiopia to investigate the influence of crop type and management on soil properties. At each site, soil samples were collected from homegardens with enset and coffee, annual-crop rotation fields, woodlots with eucalyptus, and pasture land. Thirteen soil properties were analysed for each sample, including total carbon, nitrogen and phosphorus, and available phosphorus and potassium. While geographic factors such as elevation had a significant effect on most soil properties, differences between crops within sites was the main source of variability. In general, homegarden fields (with enset and coffee) had higher soil fertility and soil carbon than the annual-crop fields, eucalyptus plots and pastures. In addition, homegarden fields and annual-crop fields with organic amendments (mainly cow manure) were found to have higher active carbon, and available phosphorus and potassium. Overall, differences in soil fertility between crops appeared to be both due to specific management and practices, in particular organic inputs, and to inherent differences between crops. Thus, the extent of the more productive and fertile homegarden crops is likely to be limited by the availability of organic amendments. This study suggests that promoting the expansion of intensive systems such as enset homegardens with the aim of improving production, soil fertility and carbon sequestration is a viable route only if management and production constraints are also taken into account.

Modern agriculture faces the dual challenge of meeting the escalating global food demand amid the degradation of more than 40% arable soils, which elevates dependence on mineral fertilizers. An alternative solution is proposed through the valorization of agricultural residues, serving as soil substrates or supplements [1,2]. Biochar, a carbonaceous product from residual biomass pyrolysis, has emerged in the last decade as a promising soil amendment. It enhances soil physical properties, promotes plant productivity, and contributes to C sequestration [3,4].

This study evaluates the effects of olive waste biochar and traditional green compost as organic amendments on soil properties, crop productivity, plant physiology, and soil respiration in a super-intensive arbequina olive plantation under deficit irrigation. Ninety-six 1m<sup>2</sup> plots, each surrounding an olive tree, were established with treatments including olive-waste biochar, green compost, a biochar-compost mixture (50% w/w), and un-amended controls (24 plots per treatment). Biochar significantly increased soil water holding capacity, reduced compaction, and improved photosynthesis, water-use efficiency, and electron transport rate, resulting in a 15% increase in olive fruit yields. However, the net oil yield per tree remained similar due to higher moisture content in olives from biochar-amended trees. Biochar application notably increased soil organic C content, particularly recalcitrant C, while soil respiration rates varied seasonally with temperature, with compost treatment showing the highest rates. The compost+biochar amendment disrupted this trend.

Fertilization impacts the conversion of microbe-derived and plant-derived carbon in particulate organic matter (POM) and mineral-associated organic matter (MAOM), affecting the storage and stability of soil organic carbon (SOC). However, how fertilization influences the microbial mechanisms underlying this conversion in paddy soil is unclear. Thus, amino sugar, lignin and enzyme activities were determined in a 12-year field experiment. Organic fertilizer increased the SOC content by 33.01%, and combined organic and inorganic fertilizers increased SOC stability by 7.07%. Specifically, organic fertilizer increased the lignin content by 17.09% (particularly in POM) and decreased the (Ad/Al)<sub>v</sub>, indicating the selective preservation of lignin. The increased bacterial PLFA/fungal PLFA and Ln(cellulase)/Ln(ligninase) demonstrated a shift of microbial communities towards bacteria and a decrease of lignin utilization. The microbial necromass carbon (MNC) content increased by 46.75% (particularly in MAOM), and the GluN/MurN decreased, showing organic fertilizer increased the contribution of MNC to SOC (especially bacterial necromass). The increased microbial biomass carbon (MBC) and r-strategy bacterial relative abundance indicated the promotion of fast-growing microorganisms. Therefore, SOC sequestration was improved with the increase of lignin and amino sugars under organic fertilizer. Combined organic and inorganic fertilizers decreased the lignin content by 11.20% (particularly in POM) and increased the (Ad/Al)<sub>v</sub> in MAOM, indicating the acceleration of lignin decomposition. Compared with other fertilization treatments, the increment of Ln(cellulase)/Ln(ligninase) and bacterial PLFA/fungal PLFA were smaller, showing a stronger promotion on fungi and lignin use. The MNC increased by 45.26% (particularly in MAOM), but the GluN/MurN was lower than that of other fertilization treatments, showing combined organic and inorganic fertilizers increased the contribution of MNC to SOC (especially fungal necromass). The increased MBC and relative abundance of r-strategy bacteria and k-strategy fungi, indicating the promotion of both fast-growing and slow-growing microorganisms. Therefore, the increase of MNC and the decrease of lignin improved the stability of SOC. Overall, fertilization regulated the conversion of plant-derived and microbial-derived carbon affecting the storage and stability of SOC.

Soils play a key role in regulating atmospheric concentrations of greenhouse gases and specially forest soils, which store around 20% of the continental organic carbon stock. Ongoing climate change could alter the balance of this stock, and the effect of temperature on soil carbon fluxes remains an important question. Q10 parameter was calculated for 4 different forest stands (beech, spruce, douglas fir and silver fir) to estimate the soil organic matter sensitivity to temperature. Soil organic carbon stocks and forestry data (volume, basal area and dead wood) were also estimated.

The mont Beuvray site (Morvan, France), a 1,000 ha mid-mountain area, homogeneous in geology and pedology, was selected. In mont Beuvray, beech correspond to historical stand, while softwood forests have been introduced over the past 70 years. Twelve soil samples per tree species (0-20 cm) were collected and the main physicochemical characteristics were determined. The Q10 was calculated for a temperature range of 5 to 25°C at laboratory.

Results show that soil organic carbon and water-extractable organic carbon contents are higher in silver fir and beech soils than in Douglas fir soils. However, the average soil carbon stocks are not statistically different between the stands. Q10 values are higher for beech ( $2.8 \pm 0.1$ ) than for the softwood species ( $2.6 \pm 0.1$ ), suggesting that CO<sub>2</sub> emissions from soil in beech stands would increase strongly with temperature than in other species.

In conclusion, several decades after the introduction of softwood species, we did not measure significant difference in carbon stocks. However, CO<sub>2</sub> emissions and Q10 values are different and related to forest species. Hence, beech soils could see their CO<sub>2</sub> emissions increase as they are the most sensitive to temperature. Conversely, silver fir stands, with their lower sensitivity to temperature, could be of interest in mitigating emissions. These results need to be confirmed by field data on soil respiration and compared with above-ground forest biomass and stand health.

**SOWING SUSTAINABILITY: A CASE STUDY ON THE IMPACT OF SUSTAINABLE LAND MANAGEMENT ON SOIL CARBON SEQUESTRATION AND CARBON FARMING IN TRIBAL REGION OF ARAKU IN THE EASTERN GHATS OF INDIA**

A. BIREK

unique land use GmbH, Freiburg, GERMANY

India, with its diverse agro-climatic zones, is a microcosm of the global agricultural land-scape, facing the dual challenge of ensuring food security for its burgeoning population while mitigating the environmental impact of farming practices. This case study investigates the adoption and impact of sustainable agricultural land management practices (SALM) in the tribal hilly region of Araku (Eastern Ghats of India), shedding light on the intricate balance required to achieve both productivity and environmental conservation.

The case study investigates the impact from diverse SALM practices on the sequestration of carbon in the soil. These practices include agroforestry with fruit and shade coffee systems, intercropping of legumes and millets, green manuring, and the use of mulching and organic composting techniques. The implementation of these activities will achieve multiple objectives, including increased carbon sequestration, improved soil fertility, increased biodiversity, and food security, thereby improving the livelihoods and well-being of indigenous landowners. SALM supports biological investments in the soil to make it more dynamically fertile and nutrient-rich so that external input requirements each year keep decreasing; it nurtures water retention and other natural resources in the environment.

Another component of this case study is the formation of a new topsoil by aggregating local biomass, composting it with microbial starter inoculants, and incorporating natural nutrient additives tailored to the regional soil physiology, such as rock phosphate, rock dusts, and oil cakes. These inoculants, when seasonally applied to the soil, introduce beneficial microbes and transform soil microbiomes.

The findings of this case study aim to contribute valuable insights for policymakers, agricultural practitioners, and researchers working towards the global goal of sustainable agriculture. By unravelling the intricacies of sustainable agricultural land management and its impact on soil carbon in the Indian context, this research aims to provide practical recommendations. These recommendations can be flexibly adapted and implemented in diverse agricultural settings around the globe, contributing to a more resilient and sustainable future for global food production.

##### DO POPLAR PLANTATIONS ENHANCE SOIL ORGANIC CARBON IN THE MEDITERRANEAN ENVIRONMENT?

<sup>2</sup> Research Centre for Wood and Forestry, CREA, Casale Monferrato, ITALY

European policies are actively promoting the adoption of Carbon farming practices aimed at sequestering CO<sub>2</sub> from the atmosphere and improving soil organic carbon (SOC) stocks in agricultural soils. Within this context, changes in land use, toward ecosystems with higher carbon (C) stock, could positively impact the global C cycle. For this purpose, we investigated the impact of the land use change from cropland (CR) to poplar plantations (PP), on the SOC stock at 0-10 cm and 10-30 cm soil depths. The time-for-space substitution method (i.e., paired comparison) was used to investigate the effect of land use change on SOC, while a spatial survey approach (i.e., SOC stock difference method) was used to evaluate the effect of thirty years of PP on SOC stock levels. This aspect was evaluated by resampling the same PP sites after a time interval of 30 years. Six farms cultivating poplar, all located in North Italy, for a total of fifteen sites, were selected for this study. Results of the land use change analysis displayed how PP maintains a larger SOC stock than CR sites, at both depths, despite a large uncertainty on the estimates. The impact of three decades of PP on SOC stock results in a positive trend, with the SOC stock increasing over time. Clustering the PP sites according to the age suggests an initial C loss occurring in the early stages after conversion of CR to PP (1-5 years) probably due to site preparation, and then the SOC increases until the end of the rotation period, overtaking the initial SOC levels. Overall, this study will pave the way for establishing an efficient management system within the framework of PP for the long-term storage of carbon in soil, thereby aiding in the mitigation of the impacts of climate change.

##### CARBON-FARMING PRACTICES FOR EUROPEAN CROPLAND: A REVIEW ON THE EFFECT ON SOIL ORGANIC CARBON

G. ANTONIELLA<sup>1</sup>, M.V. CHIRIACÒ<sup>2</sup>

<sup>1</sup> University of Tuscia, Department for Innovation in Biological, Agro-food and Forest Systems (DIBAF), Viterbo, ITALY

<sup>2</sup> Foundation Euro-Mediterranean Centre on Climate Change, IAFES Division, Viterbo, ITALY

Carbon farming has been recently proposed as an effective measure for climate change (CC) mitigation through carbon (C) sequestration or C emissions reduction. To identify and estimate the CC mitigation potential of Carbon-farming practices on European croplands we conduct a systematic review of both relative and absolute annual soil organic carbon (SOC) stock change ( $\delta$ SOCREL;  $\delta$ SOCABS) related to sole and combined agroecological practices tested on mineral soils at 0-30 cm and >30 cm soil depths. We compiled a dataset with 513  $\delta$ SOC rates expressed as Mg C ha<sup>-1</sup> yr<sup>-1</sup>, obtained from 105 experimental studies and representing 10 C-farming practices: cover crops (GM/Mu), organic amendments (OA), crop residue maintenance (R), improved rotations (IR), establishment of hedgerows (HEDGE), silvoarable systems (SLA), reduced soil disturbance (RSD), organic (ORG) and conservation agriculture (CONS) and set-aside (SET-ASIDE) or conversion of cropland into permanent grassland (G/P). Our analysis reveals a median  $\delta$ SOCREL of 0.16, 0.17, 0.25, 0.26, 0.33, 0.33, 0.38, 0.70, 0.77, 0.82, 1.08 Mg C ha<sup>-1</sup> yr<sup>-1</sup> at 0-30 cm for R, RSD, IR, SLA, OA, GM/Mu, CONS, G/P, ORG and SET-ASIDE respectively. SOC sequestration was detected only for OA, GM/Mu, CONS, ORG, and combined C-farming practices for which we estimated a median  $\delta$ SOCABS ranging between 0.32 and 0.96 Mg C ha<sup>-1</sup> yr<sup>-1</sup> at 0-30 cm. Permanent grasslands and pastures were negatively affected by any type of land-use change, at least in topsoil. Natural ecological successions after cropland abandonment (20-year set-aside), are promoting a relative SOC stock annual increase by 1.08 Mg C ha<sup>-1</sup> yr<sup>-1</sup>, while the net CC mitigation remains unclear when the subsoils are included in the assessment. In conclusion, whole soil profile SOC measurements, long-term experiments, and the SOC stock difference method should be encouraged within experimental protocols aimed at identifying C-farming practices and estimating their SOC sequestration or SOC emission reduction potential.

##### EFFECT OF BIOCHAR ON SOIL RESPIRATION IN A CULTIVATED SOIL UNDER CONVENTIONAL AND MINIMUM TILLAGE IN ZAMBIA

I. MUKUMBUTA <sup>1</sup>, V. SHITUMBANUMA <sup>2</sup>, G. NYBERG <sup>3</sup>

<sup>1</sup> GOLDEN VALLEY AGRICULTURAL RESEARCH TRUST, LUSAKA, ZAMBIA

Increasing soil organic carbon (SOC) and reducing its loss through soil respiration (SR) is a major challenge in African soils and globally. Biochar has been reported to have the potential to increase SOC through direct carbon addition and the reduction of the decomposition of pre-existing SOC, heterotrophic respiration (RH). However, the effect of biochar in combination with other soil management practices such as fertilization and tillage is not well known. Further, there is a scarcity of data in Africa on the impact of biochar and other management practices on soil C dynamics such as carbon dioxide (CO<sub>2</sub>) emissions. In this study, we assessed the effect of biochar (2 tons/ha) on RS and RH in a winter wheat field with and without NPK fertilization and under conventional tillage (discing) and minimum tillage (direct seeding) in Zambia. Fluxes of CO<sub>2</sub> were measured weekly over a 3-and-a-half month growing season using the EGM5 carbon dioxide analyzer in planted (for RS) and bare (for RH) plots. Furthermore, substrate-induced respiration (SIR) was measured in unfertilized plots for 5 hours after application of sucrose under field conditions.

Results showed that the response of RS to biochar was dependent on both the tillage method and fertilization. Biochar reduced both RS and RH under conventional tillage in the fertilized plots by 12-20%. However, without fertilization, biochar marginally increased RS and RH. Under minimum tillage, the effect of biochar on RS and RH was not significant with or without fertilizer application. Substrate-induced respiration was higher in biochar amended soils under minimum tillage, but not under conventional tillage. Our results suggest that the effect of biochar is influenced by the tillage practice and nitrogen fertilization. Further studies are needed to validate these results in different soil types and also under different agroecological zones in Zambia.

Increasing soil organic carbon (SOC) stock in agricultural soils contributes to mitigating climate change and to achieving climate neutrality goals. Furthermore, higher SOC levels may improve resilience against climate change impacts by increasing biological activity, nutrient turnover rates, infiltration rates, and water holding capacity.

However, carbon farming measures are associated with direct and indirect costs, which hamper large-scale implementation. Soil carbon certificates sold as voluntary emission offsets have emerged as a private governance tool that could offer a way to overcome these barriers and motivate sustainable transformation. In spite of a high interest from industry and farmers, the suitability of these certificates as a tool for climate change mitigation is currently under debate. To address the existing knowledge gaps, we assessed the suitability of soil carbon certificates for mineral soils from the perspectives of soil science, agriculture, and governance. With regards to the policy framework, we focused on Europe while for examples of certification providers, we used Germany as a test case.

We found that the analyzed soil carbon certificates are unsuitable to offset greenhouse gas emissions, as the permanence of carbon removals can not be guaranteed by the certification providers, and re-emission of unspecified amounts of CO<sub>2</sub> after the contracting period is highly likely. Furthermore, long-time monitoring is typically lacking, additionality is not ensured, and safeguards against leakage effects are insufficient. We conclude that current soil carbon certificates are unlikely to provide the climate change mitigation they promise and that funding for emission offsets should be used more effectively elsewhere. Finally, we compare the analyzed schemes with certification schemes based on the rewetting of organic soils and discuss if and how the planned European framework for carbon removal certification could remedy the shortcomings we identified.

Fire significantly influences the structure and functioning of savanna ecosystems and the aboveground vegetation dynamics, however the impact of fire on belowground processes is much less understood. Fire intensity and frequency is increasing with global change and thus it is vital to understand the effect of changing fire regimes on soil microbes and biogeochemical cycling in savanna ecosystems. Here, we studied the impact of different long-term fire regimes on microbes in sandy soils using the Experimental Burn Plots in Kruger National Park, South Africa. We determined how soil abiotic and biotic properties varied across differing fire intensity and frequency regimes. Our results show that fire regime had no effect on soil carbon, nitrogen or pH and limited impact on microbial community composition and biomass. Given that there were negligible differences in soil properties between fire regimes and very low concentrations of soil microbes across all soils, we also investigated whether soil microbial function was affected. This was quantified using assays of moisture and carbon limitation on microbial activity. Whilst increasing water availability had no impact on soil respiration, substrate-induced respiration rates were significantly greater with higher intensity fires than lower intensity fires and fire suppression, suggesting potential differences in the microbial functional groups contribution to rapid carbon-cycle responses between fire regimes. Overall, our findings highlight the resilience of this system to prescribed fire variance and provide understanding on microbial interactions with fire in savanna ecosystems. This is an essential study for informing long-term fire management strategies and savanna biome conservation.

<sup>3</sup> Assessment, Restoration and Protection of Mediterranean Agrosystems Service (SERPAM), Estación Experimental del Zaidín,, Granada, SPAIN

Grasslands biomes are globally threatened by woody plant encroachment. Pyric herbivory -the combination of prescribed burnings and targeted grazing- is an efficient tool to restore open habitats and to promote diversity. However, how pyric herbivory practices affect belowground biodiversity is less well understood. We assessed the midterm effects on soil bacterial and fungal populations of prescribed burns and targeted horse grazing applied as restoration measures against gorse expansion (*Ulex gallii* Planch.). We set up three treatments in two shrub-encroached grasslands in the western Pyrenees: burning but no grazing, burning and grazing, and no burning and no grazing as control. We collected topsoil samples (0-3 cm) at two dates: D1, immediately following the burning (n=20, 10 not burned + 10 burned), and D2, 1.5 years later, following two periods of horse-targeted grazing (n=24, 8 not burned not grazed + 8 burned not grazed + 8 burned and grazed). Soil DNA was isolated and DNA metabarcoding was performed targeting an ITS genomic region for fungi and a 16S genomic region for bacteria. Bacterial and fungal populations responded differently to burning. Heat maps and hierarchical clustering from D1 showed that bacterial populations at the two sites were grouped together and that they evolved differently after the burning. On the contrary, fungal composition was initially different at the two sites but evolved to a more similar fungal community after the burning. Heat maps and hierarchical clustering from D2 showed that grazing after burning lead to a similar bacterial and fungal composition in both sites. Following the fire, the prevalence of the fungi *Pezoloma* and *Phomatospora* surged in the burned plots. However, after two grazing periods, equivalent to 1.5 years, a different set of fungi - *Conochieta*, *Nadsonia*, and *Pochonia* - along with the bacteria *Sphingomonas* and an unclassified *Rizhobiales*, showed an increase in the burned + grazed plots.

Grants PID2020-116786RB-C31 and PID2020-116786RB-C32 funded by AEI (Ministerio de Ciencia e Innovación/ES/Grant #10.13039/501100011033)

#### EVALUATION OF SOIL QUALITY INDICES UNDER DIFFERENT TYPES OF DAIRY SYSTEMS IN COLOMBIA

W.A. CARDONA, L.G. BAUTISTA, J.C. BENAVIDES, P.J. CRIOLLO, D.R. TORRES, M.M. BOLAÑOS

AGROSAVIA C.I TIBAITATA, MOSQUERA, COLOMBIA

Livestock in Colombia is developed over large areas; in 2022, nearly 29,301,392 animals distributed in 633,841 farms were reported. Traditional livestock systems with low technological implementation generate negative impacts on soils, by affecting their physical and chemical properties, which leads to the need to develop and implement sustainable livestock farming. Considering the above, this research evaluated the effect of three plots (treatments) established under a split-plot design with different grazing practices for dairy cattle farming (pasture renewal, silvopastoral, and traditional) on the physical and chemical properties of soil located in the municipality of Saboyá (Boyacá, Colombia). Soil sampling was carried out during 2015 (baseline), 2016, 2017, and 2022 to determine their physical and chemical characteristics. The laboratory results were used for the design of soil quality indices (SQI), which required the selection of a minimum set of properties through principal component analysis (PCA), the application of the method known as an expert opinion (EO) to validate the PCA results, and the calculation of the additive and weighted indices. The indices obtained were subjected to a least squares test with multiple comparison adjustments according to Tukey of the SAS Enterprise 8.3 software, in order to evaluate the effect of different types of dairy systems and their interaction with the years evaluated. Finally, using geostatistical tools from ArcGIS® Pro 2.9.0 (ESRI®) software, the deterministic spatial interpolation method IDW (Inverse Distance Weight) and Moran's Index, the obtained indices were cartographically represented. The indices from 2015 to 2017 were high compared to those of 2022, which were moderate, showing the impact of livestock farming on the soil and confirming the importance of sustainable livestock practices. Similarly, preparing maps using soil quality indicators built from different physical and chemical properties becomes a valuable tool to identify areas with the greatest need for intervention.

#### HOW DOES GRASSLAND PRODUCTIVITY RELATE TO SOIL CARBON SEQUESTRATION: THE EFFECTS OF FERTILIZER DRIVEN DIFFERENCES IN YIELD ON MOUNTAIN GRASSLAND C STOCKS

M. VOLK<sup>1</sup>, E. FILIPPINI<sup>1,2</sup>

<sup>1</sup> Agroscope, Climate and Agriculture, ZURICH, SWITZERLAND

<sup>2</sup> University of Zurich, Dept. Geography, Soil Science and Biogeochemistry, ZURICH, SWITZERLAND

We generated six distinct productivity levels in a mountain hay meadow at 1200 m asl. in the Swiss Alps, using non-N mineral fertilizer applications. This grassland field experiment was continuously under the same management for 32 yrs. Applying both a carbon (C) stocks analysis and a C fluxes analysis, we investigated the effect of aboveground yield on the ecosystem organic carbon (OC) budget.

Fertilization promotes plant growth and plant growth provides the OC that may become stabilized in the soil. We hypothesized that harvested yields are a valid proxy for the amount of plant derived OC that enters the grassland ecosystem. Everything else being equal, this would result in larger soil organic C (SOC) stocks, increase the terrestrial sink for CO<sub>2</sub> and thus reduce the [CO<sub>2</sub>] increase rate in the atmosphere.

We found that between fertilization categories grassland yields differed by factor 1.4- 2.0, depending on the reference period (30 yr. mean vs. single year). Surprisingly, SOC stocks did not differ between fertilization categories.

Paralleling a 1.5°C mean annual warming, grassland yields have decreased by ca. 25% over the 32 yrs. period, while the yields were reduced further in years with pronounced summer heat, despite the high altitude of the site. During the same time, SOC stocks decreased by 15% on average.

Parameterization of the net ecosystem C flux balance, based on year-round CO<sub>2</sub> gas exchange measurements, closely matched the C stock based balance. It suggests proportionally higher respiration rates in high yield fertilization treatments. Thus, in high yield grasslands the higher ecosystem OM input is apparently driving a higher decomposition rate, rather than increasing the SOC stock.

We conclude that yield increases of agricultural grasslands do not serve as good proxies for a concomitant increase in SOC stock. Analogously, agricultural management practices, aiming at increased soil C sequestration rates, may focus rather on lower OM decomposition rates (C output) than on higher OM production rates (C input).

#### WILL CONSERVATION TILLAGE COMBINED WITH THE LAND APPLICATION OF BIOCHAR 'SEQUESTER' CARBON IN THE TROPICAL SOILS OF SOUTHERN GUAM?

G. MOHAMMAD H, M.H. GOLABI, F.P. GALSIM, K.R. PEREZ

University of Guam, College of Natural and Applied Sci., Soil Labs, Mangilao, GUAM

In our previous studies we have reported that soil organic carbon depletion caused by soil degradation as the result of mismanaged cultivation, and soil disturbances negatively impacts soil health and soil quality thus reduces soil productivity and threatens the agricultural sustainability. Furthermore, carbon dioxide (CO<sub>2</sub>) which is also produced by soil carbon reaction to the atmospheric air as the soil surface becomes exposed to air due to disturbances such as extensive tilling could possibly contribute to climate change scenario. On the other hand, a larger portion of soil carbon can be stored in the soil via land-based management techniques and by implementing carbon 'sequestration' practices thus reducing the effect of carbon dioxide (CO<sub>2</sub>) emission on global warming.

Adoption of any conservation practices that retain the organic carbon in the soil, hence reducing the risks of carbon loss into the atmosphere in the form of CO<sub>2</sub> emission must be considered seriously. Additionally, adoption of practices such as the application of 'biochar' as a soil amendment that may potentially 'Sequester' carbon in the soil biota must also be considered as a management strategy to reduce the amount of CO<sub>2</sub> coming off the soil upon soil surface disturbances. Therefore, in addition to practicing conservation tillage practices, we are also evaluating the effect of 'biochar' application as a soil amendment for improving the carbon storage capacity of the soils under study.

In this presentation, we will report the result of the land management practices including the land application of 'biochar' and its effect on the dynamics of soil carbon content and the soil carbon storage capacity on severely degraded soils of Guam. We also report the carbon loss from the soil under the conventional tillage as compared to the conservation practices (i.e., no-till) and their effect on soil carbon and for reducing the CO<sub>2</sub> emission into the atmosphere.

Anthropogenic activities profoundly impact soil organic carbon (SOC), affecting its contribution to ecosystem services such as climate regulation. Here, we conducted a thorough review of the impacts of land-use change, land management, and climate change on SOC. Using second-order meta-analysis, we synthesized findings from 230 first-order meta-analyses comprising over 25,000 primary studies. We show that (i) land conversion for crop production leads to high SOC loss, that can be partially restored through land management practices, particularly by introducing trees and incorporating exogenous carbon in the form of biochar or organic amendments, (ii) land management practices that are implemented in forests generally result in depletion of SOC, and (iii) indirect effects of climate change, such as through wildfires, have a greater impact on SOC than direct climate change effects (e.g., from rising temperatures). The findings of our study provide strong evidence to assist decision-makers in safeguarding SOC stocks and promoting land management practices for SOC restoration. Furthermore, they serve as a crucial research roadmap, identifying areas that require attention to fill the knowledge gaps concerning the factors driving changes in SOC.

<sup>3</sup> Centro de Investigación en Suelos Volcánicos, Universidad Austral de Chile, Valdivia, Chile, Valdivia, CHILE

Based on the proposal of Vogel et al. (2019) separating the C content in potential and actual state, we have adapted the quantification of this function using a soil reactivity index (aluminum extracted with 1M of ammonium acetate pH 4,8; 1:10 soil extractant ratio) instead of clay plus half of silt content. The modeling was based on the relation of soil reactivity index and C content of 1660 soil samples data collected from agricultural and grassland soils throughout all the country. To evaluate Chilean Patagonia from the Aysen Region were used (173 superficial soil samples) from Entisols, Mollisol, Spodosols, Andisols, Inceptisols and Organic soils. For each point the potential capacity to store organic C was estimated ( $C_p$ ; kg C m<sup>-2</sup>) and a relative index of this capacity ( $I_{soc}$ ; 0 to 1) to compare among individual sampled points. Also, we estimate the actual state ( $C_s$ ; kg C m<sup>-2</sup>) with a relative index ( $\hat{I}_{soc}$ ). We categorized.  $I_{soc}$  values greater than or equal to 0.5 as moderate to high storage potential, while those lower indicate lower storage potential.  $\hat{I}_{soc}$  values greater than 1 denote fragile soils (Clunes et al. 2022), while those between 0 and 1 were characterized relative to C saturation levels as very low, low, medium, high or very high.

Results showed that the Aysen region has an  $C_p$  average 52.5 kg m<sup>-2</sup> of C, with an  $I_{soc}$  value of 0.6 on average. The  $C_s$  reached only 28.9 kg m<sup>-2</sup> of C, with an  $\hat{I}_{soc}$  average value of 1.3. Of the total samples evaluated 24 % were considered in a fragile condition because they accumulate an average of 11.8 kg m<sup>-2</sup> above the estimated saturation level meaning that C was accumulated as residues or fibric C as peats and bogs, while 55% of the non-fragile soils were in a high and very high condition respect to its estimated saturation level.

Rapid increase in oil palm cultivation has caused environmental pollution and greenhouse gas (GHG) emissions, such as carbon dioxide (CO<sub>2</sub>) and nitrous oxide, due to land use change and fertilization. Burning empty fruit bunches (EFB) as fuel in oil palm mill has negative impacts on air quality and boiler because of high content of potassium (K) and other components. Thus, alternative means on effective EFB utilization are necessary for carbon-neutral systems. Washed EFB can be processed as fuel pellets for biomass power generation and EFB washing water (ww) can be used as liquid fertilizer. EFB ww has high soluble C and K levels which can enhance palm growth and soil microbial activity. Effect of EFB ww on microbial activity and CO<sub>2</sub> production, emissions and palm yield were evaluated for sustainable soil management.

Trenches were dug in an oil palm plantation near Kuantan, Malaysia. Soil layer samples (0-40 cm+) were collected along its cross section and measured for three-phase analysis and total C after 2 years of EFB ww application comparing to tap water (control). Soil microbial ATP and its activity, CO<sub>2</sub> respiration rate were measured. CO<sub>2</sub> fluxes were also measured from soil surface and the soil bottom of trenches by chamber method.

Three-phase analysis showed that the liquid phase decrease and the solid phase increase toward the lower layers. Soil ATP was higher with EFB ww than the control. CO<sub>2</sub> flux from the soil surface was higher than that from the bottom of trenches. CO<sub>2</sub> flux from EFB ww plot was higher than the control, possibly because soil microorganisms are more active with EFB ww. Porosity and respiration rates increased in the surface layer compared to before the EFB ww was poured, indicating that microbial activity was promoted by application of EFB ww. Oil palm yield had no decline in dry season, where soil C increased in the lower layer, suggesting a carbon sequestration effect.

Carbon neutrality is considered as the key strategy for climate mitigation. Cities which are responsible for a major part of anthropogenic C emissions invest in development of urban green infrastructures (UGI) to compensate these emissions by C sequestration in biomass. The role of urban soils in UGI C balance remains overlooked resulting in uncertainty in the estimated capacity of UGI to accumulate and store C. In fact, urban soils can be considered a social-ecological phenomena since direct and indirect anthropogenic drivers have the main impact on soil functionality and ecosystem services including C sequestration.

The research integrates two case studies, where direct and indirect anthropogenic effects distinguished spatio-temporal patterns in C stocks in and CO<sub>2</sub> emission from urban soils. The first case study focused on the effects of urban mesoclimatic anomalies and soil construction practices in Murmansk (polar zone) and Moscow (temperate zone) cities in Russia. In both cities, urban heat island (UHI) effect accelerated CO<sub>2</sub> emissions from urban soils. In Moscow city center, where implementation of peat-sand mixtures coincided with the strongest UHI, CO<sub>2</sub> emissions increased up to 30-40% compared to the reference cities. The second case study compared environmental and social drivers of spatial variability in soil C stocks in Wageningen, the Netherlands. The study included several scales. First, a random stratified soil survey (n=56) was done for the whole city to capture the effect of parent materials, land cover and land-use history. Afterwards, effect of the social factor was studied by expert interviews with the owners of the green areas (key plots, n=10), where detailed soil survey was done. Finally, the effects of UGI maintenance practices were studied for the case of university campus. Land-cover and land-use history distinguished spatial patterns in soil C at the city level, whereas at the local scale social factors dominated.

Arable soils were seen as essential for global food security, but now other functions, particularly their potential to store large amounts of carbon (C), are receiving more attention. Recently, there have been increasing efforts to increase soil organic C sequestration as climate change mitigation effort, as prominently promoted by the 4per1000 initiative. However, to evaluate soil C sequestration in hilly terrain, it is necessary to consider lateral soil redistribution in addition to changes in vertical C fluxes (C input and/or reduced mineralisation). Tillage erosion has been found as an important contributor to soil redistribution and modulator of C dynamics. Nevertheless, most studies dealing with SOC redistribution still focus on water erosion. This study investigates the impact of tillage erosion on C fluxes in an intensively cultivated loess region in the Czech Republic. The coupled water and tillage redistribution and C turnover model SPEROS-C was used to analyse the effect of six decades of erosion upon C fluxes, whereas a specific focus was set to the analysis of the importance of tillage erosion.

Our results show that tillage erosion is a major contributor to C dynamics in our area, particularly on slope shoulders where a substantial decline in C was modelled and monitored. Even if water erosion is the dominant process in the region, the model results reveal that tillage erosion increased the cumulative, erosion-induced C sequestration potential by about 37%. Furthermore, it is interesting to note that tillage erosion reduced the total sediment delivery from the monitoring site via a change in topsoil C patterns and hence, water erosion induced sediment transport. In the highly productive loess region, tillage erosion led to substantial C sink since agricultural mechanisation substantially increased about six decades ago. The climate mitigation measures based on adapted agricultural management to increase C sequestration are often in-line with soil conservation measures. This indicates that it might be less effective as the erosion-induced C sink effect declines.

Soil is a vital, limited, and non-renewable resource. The significance of healthy soils is widely recognized to increase our resilience to withstand the impacts of climate change and extreme weather events, including droughts and floods. Overall, healthy soils play a fundamental role in underpinning our well-being. The decline of organic carbon (OC) is considered as a primary 'threat' to soil health, a concern that is especially pronounced in the Mediterranean region. The role of OC in soil quality and functioning, as well as in the ability of agriculture to adapt to climate change are well-documented. These aspects are integral components of programming tools for shaping regional agricultural policies, which include measures to promote resource-conserving agronomic practices. In this regard, the availability of estimates of OC dynamics offers valuable insights for comparing different spatial planning strategies, at the regional level. Depending on the accessibility and level of accuracy of the input data, different procedures can be adopted to assess OC dynamics in relation to soil, climate, land use and land-use change. This study presents an example of applying the RothC10N model to simulate OC dynamics in a ten -year period window (2004-2013) at the local detailed scale in Apulia region (southern Italy). RothC10N was chosen due to its reliability and robust outputs with minimal input data, distinguishing it from other predictive and more complex models. RothC10N requires point-specific basic and physical pedological data, information upon climate and crop succession along with soil management. In addition, the model's batch mode capability allows for large-scale processing of spatialized input data. Here, we discuss OC dynamics simulations produced by both point specific and recursive RothC10N spatial applications, highlighting the pros and cons of these two methodologies. Identifying the most suitable modeling approach is crucial for accurately mapping and estimate the potential of OC sequestration for different soil-climate-crop-management systems and providing to the stakeholders an essential tool to take informed and sustainable management decisions.

**DOES SLOVENIA'S AGRICULTURAL LAND HAVE THE POTENTIAL TO SEQUESTER ORGANIC C AND ACHIEVE THE 4PER1000 TARGET?**

S. MAVSAR, H. GRČMAN, R. TURNISKI, R. MIHELIC

University of Ljubljana, Biotechnical faculty, Ljubljana, SLOVENIA

Enhancing soil management practices is a key strategy to address future climate change impacts, as soil is a significant reservoir of organic carbon. Maintaining or increasing soil organic carbon (SOC) can help mitigate climate change by sequestering carbon from the atmosphere. The aim of our study was to assess SOC stocks in different Slovenian agricultural soils and to investigate potential sequestration in fine soil fractions (<20 µm) and total soil mass at 0-10, 10-20 and 20-30 cm depth. From 2016 to 2020, as part of the MAFF-funded initiative, soil sampling campaigns were conducted covering different agricultural lands such as cropland (CR), vineyards (VI), intensive orchards (IO), extensive orchards (EO), grassland (GR), overgrown grassland (OG) and areas densely covered with trees and bushes (TB). Using Hassink's (1997) model, we determined the carbon sequestration potential (SCS) of the fine fraction (C<sub>sd</sub>), incorporating soil texture data and factors from Chen et al. (2018). The total SCS potential of soil mass was calculated using the IPCC Tier 1 method considering different soil management scenarios. The average SOC stock in Slovenia based on land use data for 2019 is 94.7 t ha<sup>-1</sup> in the 30 cm layer. It is noteworthy that CR, IO and VI have the highest C<sub>sd</sub> in the top 10 cm, while GR, OG and TB have the lowest values. To meet the 4per1000 initiative, we recommend the transition from full inversion to no-till in cropland, the adoption of organic farming principles and/or the use of conservation agriculture. For plantations such as VI, IO and EO, maintaining permanent vegetation cover in interrows, avoiding deep tillage and leaving grass and prunings on the soil surface or incorporating them superficially into the soil is recommended. Sustainable management practices for GR include light to moderate grazing or cutting, coupled with improvement measures. Implementing these practices could increase the average SOC stock by 19.6 t ha<sup>-1</sup> over 20 years, a commendable annual improvement of 10.3per1000.

#### MODELING SOIL ORGANIC MATTER DYNAMICS IN COCOA FARMS

T. FUNGENZI <sup>1</sup>, S.D. KHALSA <sup>1</sup>, P.J. BURGESS <sup>2</sup>, R. SAKRABANI <sup>2</sup>

<sup>1</sup> Mars Wrigley Science and Technology, Davis, USA

<sup>2</sup> Cranfield University, Cranfield, UNITED KINGDOM

Improving our understanding of soil organic matter (SOM) dynamics is crucial for enhancing soil fertility and mitigating climate change. Modeling can help us understand SOM variations over time, especially in understudied systems like cocoa farms. This study aims to model SOM dynamics in Indonesian cocoa farms, hypothesizing that the general trend is an initial rapid SOM decline post-planting followed by a gradual long-term accumulation. To test this hypothesis, we adapted the AMG soil model (Clivot et al., 2019) to a cocoa perennial system calibrated using data from 13 Sulawesi cocoa farms. The model was used to quantify organic inputs required to counteract SOM losses, considering a significant SOM mineralization coefficient (0.125 yr<sup>-1</sup>) in the local context. The outputs showed a marked SOM decrease in the initial years after planting, underscoring the critical need for substantial organic inputs to mitigate SOM depletion during this period. The model's accuracy was affirmed by a reasonable fit with farm dataset observations (0-20 cm depth) exhibiting a root mean square error (RMSE) of 19.22 Mg SOM ha<sup>-1</sup>. The study suggests that immediate post-planting years are pivotal for SOM management in tropical cocoa farms. While the model offers a promising approach to simulate SOM dynamics in tree crops, further validation with true-time chronosequences is essential. Opportunities for enhancing the model's representativeness are also discussed.

<sup>3</sup> COLEGIO DE POSTGRADUADOS, TEXCOCO, MEXICO

The main characteristic of the Mountain Cloud Forest (MCF) soils is the depth of their surface horizons that characterize them. The soils of these forests have been recognized for their high potential to store and stabilize organic carbon, with the consequent formation of clay-humus complexes in their aggregate structure. However, there are few studies focused on understanding the interaction that soil organic carbon (SOC) has on the stability and formation of soil aggregates in these ecosystems. In light of the above, the transformation and mineralization of soil organic matter was studied, evaluating the SOC fractions in the macro, meso and micro aggregates and relating them to the structural stability and their micromorphological arrangement through their degree of evolution, in MCF's. of the "Sierra Gorda" Biosphere Reserve in the municipality of Jalpan, Querétaro. The SOC stabilization processes and storage were obtained through the humification degree indices (HDG), the proportion of free and bound organic carbon (OC), separation of intra-aggregate particulate organic matter (i-POM), aggregate stability (AS). The transformation processes of the different carbon fractions are described, and their relationship with the soil aggregation process in epipedons, describing the structure based on chemistry and micromorphology in thin sections. The data obtained were analyzed in one-way ANOVA in R statistic, non parametric Wilcox and au b Kendall test in SPSS 2.5, to find differences in aggregation and OC for each of the sites and horizons. The proportion of the i-POM is microaggregates > mesoaggregates > macroaggregates and the C fulvic acid fraction was the dominant one in the humic substances. The high stability of the aggregates of the three mollic epipedons is related to the physical protection of i-POM and the SOC store in fulvic acids that, together with the high clay content, favor its stabilization.

**Keywords:** humic substances, clay-humus, organic carbon sequestration

#### THINNING EFFECTS ON CARBON STOCKS AND SOIL PROPERTIES IN BLACK PINE PLANTATION

A. SARIMEHMETOGLU<sup>1</sup>, S.T. GUNER<sup>2</sup>, R. KARATAS<sup>1</sup>, D. GUNER<sup>1</sup>, F. ATALAR<sup>1</sup>

<sup>1</sup> Research Institute for Forest Soil and Ecology, ESKISEHIR, TURKEY

<sup>2</sup> Bartin University Ulus Vocational School, BARTIN, TURKEY

The possibility of combating global warming and climate change increases interest in terrestrial carbon sequestration. Forests stock more than 80% of terrestrial aboveground carbon and more than 40% of terrestrial subsoil carbon. The purpose of this study was to determine the effect of thinning on carbon sequestration, soil and litter properties in Black pine (*Pinus nigra* Arnold.) plantations. The study was conducted, within the borders of Akdag National Park; different thinning intensities -unthinned (control), light (15% BA), moderate (25% BA), and heavy (35% BA) were applied with three replications. Before thinning and after 5 years, breast-height diameter (DBH) and tree height measurements were conducted, soil and litter sampling was carried out in each parcel. Single tree mass equations and carbon ratios were used to calculate the tree carbon stocks in the experimental parcels. Soil (0-10, 10-20 and 20-30 cm) and litter (25x25 cm) sampling was carried out from four different points representing the experimental parcels. Litter and soil properties were determined for each experimental parcel. According to the findings, tree and ecosystem carbon stocks showed significant differences between treatments ( $P < 0.05$ ). The highest amount of C stocks in trees is 223.1 t/ha in the control treatment, and the lowest is 145.6 t/ha in the heavy treatment. The litter and soil carbon stock were found to be insignificant ( $P > 0.05$ ). Tree and ecosystem carbon stocks decreased as the thinning intensity increased. The nutrients in the litter and soil, and other soil properties, were not significantly different among thinning parcels. When examined in terms of nutrient stock in the soil and litter, a difference was detected only in the Na stock in the soil, while a significant difference was found in the N, P, K, Mg, Fe, and Mn stocks in the litter. When carbon-focused planning is considered, moderate interventions in similar areas afforested with black pine may be a better practice in forest management.

#### QUANTIFICATION OF SOIL ORGANIC CARBON STOCKS OF AGRICULTURAL SOILS IN SLOVENIA

B. VRSCAJ <sup>2</sup>, J. BERGANT <sup>1</sup>, P. KASTELIC <sup>1</sup>

<sup>1</sup> Agricultural institute of Slovenia, Ljubljana, SLOVENIA

<sup>2</sup> Faculty of Environmental Protection, Velenje, SLOVENIA

In the face of increasing concern about climate change, agricultural soils are recognised as important store of atmospheric carbon with twofold benefits: They sequester CO<sub>2</sub> from the atmosphere and improve soil quality by providing a range of ecosystem services.

The main objectives of the research were: i) to assess and map the SOC stocks of Slovenian agricultural soils, ii) to estimate the carbon sequestration potential of Slovenian agricultural soils.

Between 2016 and 2022, soils were sampled from 485 sampling sites, divided into eight different types of agricultural land use. The soils were sampled at depths of 0 – 10, 10 – 20 and 20 – 30 cm. SOC was determined using the wet oxidation method, from which SOC was calculated according to the FAO and GSP approach for calculating SOC. For SOC mapping, geostatistical modelling was performed using the regression kriging method, integrating the measured SOC data collected in the field and prediction covariate data.

The result of the GIS modelling was the SOC map of Slovenian agricultural soils at a resolution of 20x20 m. Using the stepwise method in the regression kriging approach, 11 out of 35 covariates were found to be significant for the SOC inventory. The model was able to predict 54.8 % of the variance in SOC stocks. SOC stocks in Slovenia range from 31.0 t/ha to 329.0 t/ha, with an average value of 87.2 t/ha, which means that 54.9 Mt of organic carbon is stored in the first 30 cm of agricultural soils in Slovenia. The study confirms that SOC stocks in Slovenian soils are relatively high compared to some neighbouring countries. However, with notable geographical differences.

Georeferenced data on SOC stocks provide important information where to focus on agricultural practises for sustainable soil management, soil quality protection and carbon management. The results of the study will facilitate targeted agricultural intervention measures and subsidies for carbon-emphasised soil management and carbon accounting at the national level.

#### SOIL ORGANIC CARBON CONTENT IN RELATION TO AGRICULTURAL LAND USE IN SLOVENIA

M. SCUKA, E. ZAGORAC, J. BERGANT, P. KASTELIC, B. VRSCAJ

Agriculture Institute of Slovenia, Department of Agricultural Ecology and Natural Resources (DAENR), Ljubljana, SLOVENIA

Among a number of soil physical, chemical and biotic parameters, the soil organic carbon (SOC) content is considered to be the key parameter. In Slovenia, the SOC content was comprehensively monitored until 2016. Since then, the Ministry of Agriculture, Food and Forestry has invested considerable resources to obtain information on the state of SOC content in agricultural soils of Slovenia. The aim of the study was to review legacy SOC data from the soil fertility monitoring programme and to summarise recently measured data on SOC content collected within the harmonised sampling of the new national agricultural soil monitoring programme (ASMP). Seven agricultural land uses were analysed in the study: Arable land, vineyards, intensive orchard, extensive orchard, overgrown areas, trees and shrubs. The old SOC data came from topsoil samples taken at random from farmers. As part of the ASMP, the soils were sampled, depending on the agricultural use. 999 soil samples were taken at 465 locations from two or three different depths. The SOC content was determined using the ISO XXZ method. Both SOC datasets were statistically and geospatially analysed to assess the SOC stocks in different agricultural uses. The SOC data are stored together with other soil parameters in a soil information system. The mean SOC content of arable soils is  $92.3 \pm 51.27$  t/ha, of vineyards  $59.9 \pm 19.24$  t/ha, of intensive orchard  $71.3 \pm 14.81$  t/ha, of extensive orchard  $90.6 \pm 23.68$  t/ha, of grassland  $96.6 \pm 32.70$  t/ha, of overgrown areas  $93.5 \pm 38.61$  t/ha and of trees and shrubs  $107.2 \pm 48.45$  t/ha. The SOC stocks in Slovenian soils are relatively high compared to some neighbouring EU countries. Nevertheless, they vary considerably depending on soil types and soil-climatic conditions in the Mediterranean, Alpine and continental climate zones of Slovenia. The results provide a solid basis for reporting on the national carbon balance and for the introduction of sustainable agricultural practises, conservation tillage and carbon farming.

**THERMAL ADAPTATION OF MITES DRIVES THE COMMUNITY, MORPHOLOGICAL, AND PHYSIOLOGICAL RESPONSES TO URBAN HEAT ISLAND ACROSS MAJOR CITIES IN CHINA**

B. WANG, X. SUN

Key Laboratory of Urban Environment and Health, Institute of Urban Environment, Chinese Academy of Sciences, Xiamen, CHINA

Urban heat-island-induced thermal stress is one of the most important nonbiological factors that drives biodiversity decline and functional homogenization of arthropod assemblages in urban soil. Yet, arthropods, which account for approximately 75% of animal species and consist of a variety of phenotypic traits, have never been extinct from urban green spaces, phenotypic and physiological adaptation within and across the communities might be a solution to cope with the detrimental effects of thermal stress, especially for fast-developing arthropods with limited dispersal abilities, such as acarid mites. However, this subject is poorly addressed. In the present study, we investigated whether urban heat-island affects the community composition, morphological traits, and metabolic rates of acarid mites, by collecting mites along heat-island gradients in twelve cities in tree climatic zones (subtropical, warm-temperate, temperate areas) in China. We in total collected and measured 23,130 individual mites across twelve cities, the density of mites across all cities showed a negative correlation with ground surface temperature, on the contrary, the density of mites in subtropical cities showed a strongly positive correlation with ground surface temperature, implying a stronger thermal tolerance of mites in subtropical cities than in temperate cities. Similarly, the density of all functional groups in subtropical consistently showed a positive correlation with the relative thermal intensity to urban heat island ( $\delta UHI$ ), especially for oribatida, mesostigmata, mutualistic and phoretic mites, whereas the correlations were negative for functional groups in temperate cities. In conclusion, our results suggest that urban heat-island may strongly influence the urban soil systems by shaping community composition, phenotypic traits and physiological activities of mites, which will have far-reaching consequences for the nutrient cycling and energy fluxes in urban systems.

**EARTHWORM INTRODUCTION AND MASSIVE ORGANIC MATTER INPUTS TO IMPROVE SOIL FERTILITY IN MEDITERRANEAN VINEYARDS.**

L. PETIT DIT GREZERIAT<sup>1,2</sup>, F. GAVINELLI<sup>3</sup>, M. RAULT<sup>1</sup>, C. PELOSI<sup>2</sup>

<sup>1</sup> Avignon Université (IMBE), Avignon, FRANCE

<sup>2</sup> INRAE, Avignon, FRANCE

<sup>3</sup> Università di Padova, Padova, ITALY

Soil fertility is a key concept in agronomy and agroecology, resulting from the physical, chemical and biological parameters of the environment. Biological fertility is closely linked to soil biodiversity which can promote several biological functions, especially soil engineers such as earthworms. Earthworms are able to improve soil porosity, incorporate and fragment organic matter (OM) particles and enrich soils with the production of their casts. Mediterranean vineyards soils were often found to be depleted in soil biodiversity, possibly due to low soil OM contents, contamination with copper through Cu-based fungicide, soil tillage and lack of soil cover.

An ecological engineering study was designed in 2021 with the introduction of earthworms coupled with massive inputs of OM (composted or non-composted) in French Mediterranean vineyards. Several earthworm species (i.e., *Lumbricus terrestris*, *Aporrectodea caliginosa*, *Aporrectodea nocturna* and *Allolobophora chlorotica*) were introduced and the populations have been monitored since then in the different OM treatments.

We will present the results of our field monitoring on the survival and dispersal of the introduced species in the different OM treatments. One year after earthworm introduction, one species appears to be the best candidate for vineyard soil restoration perspectives and these results were confirmed in the second year. Moreover, the uncomposted OM increased strongly earthworm density compared to the control and the others OM treatments (at least 14 times more after 2 years).

Moreover, the effects of the different OM treatments on soil parameters (i.e., copper bioavailability, soil OM content and water retention) will be shown. For instance, copper bioavailability was measured in relation to a depth gradient in order to assess how this parameter will be modulated by OM inputs on the soil surface. Benefits and drawbacks of earthworm introduction and massive organic inputs for soil fertility improvement will be discussed, as well as methodological aspects and future perspectives.

Example of massive organic inputs in French Mediterranean vineyards:

While little is still unknown about the relationship between soil physicochemical properties and soil microbial community structure, diversity and functionality, and while the effect of plethora of land uses on them have been widely dissected, the complex interactions between soil microbial properties and functionality and the human environment factors remain definitively unexplored.

Soil physicochemical properties are deeply affected by human activities, and they have been confidently recognised as the main drivers of soil microbial communities, however no data is still available on the direct effect of the “human diversity” on soil ecology. Several studies compared soil microbial ecology metrics, computed for urban, agricultural and natural forest soils but they rarely, or fairly never, pinpoint the effect of the same land use practised by different human actors neither in urban nor in rural areas.

In the context of a social research project we aimed to unravel the relationships between human communities aboveground and microbial communities underground, both taking care of the same soil types. We conducted participative research practices, involving researchers from different disciplines and common citizens to explore soil microbial communities structure, diversity and functionality. Four main agro-ecological land management types have been studied from a multiple transdisciplinary point of view and experimental sites selected to maximise their representativeness of the human environment of the study area. We practised soil metagenomics to analyse microbial diversity and litterbags NIR sage to study microbial functionality.

The same regenerative agricultural practices carried out by researchers in a “research residence” located in a marginal ancient rural area and by citizens in a metropolitan urban area were considered, unravelling their effect on the one hand on soil functional biodiversity, on the other hand on human wellbeing both for researchers and for citizens.

Soil health, a widely debated topic within both the general public and academia, is here taken as a meeting point, pursuing the ambitious objective of building bridges between researchers and citizens.

Dark chestnut and chernozem soils of Eastern Issyk-Kul are characterized as the most fertile soils of Kyrgyzstan, where high yields of grain and row crops were grown and obtained. Agricultural utilization of secured rainfed and irrigated soils by farmers and peasants after disbanding of large collective farms experienced certain difficulties. Modern study of these soils with agrochemical indicators gives an idea about their state of nutrient element supply and plan certain methods of farming system, such as soil-protective and energy-saving technologies. Agrophysical and agrochemical indicators of chernozem soils allow to apply minimal, surface tillage with observance of basic principles of soil-protective technology.

Dark chestnut and chernozem soils of Eastern Issyk-Kul are characterized as the most fertile soils of Kyrgyzstan, where high yields of grain and row crops were grown and obtained. Agricultural utilization of secured rainfed and irrigated soils by farmers and peasants after disbanding of large collective farms experienced certain difficulties. Modern study of these soils with agrochemical indicators gives an idea about their state of nutrient element supply and plan certain methods of farming system, such as soil-protective and energy-saving technologies. Agrophysical and agrochemical indicators of chernozem soils allow to apply minimal, surface tillage with observance of basic principles of soil-protective technology.

When mountain-valley dark chestnut and chernozem soils are used in farming, the input of biomass of agrocenoses (crop residues and roots) compared to natural conditions is sharply reduced, especially in case of repeated sowing of potatoes and row crops, which negatively affects the indicators of soil organic matter. With additional input of post-harvest crop residues favorable factors of soil formation in the region of distribution of mountain-valley dark-chestnut and chernozem soils of Eastern Issyk-Kul region favorably affect the fertility of arable land.

<sup>3</sup> Department of Geoscience, UFMA, São Luís, BRAZIL

According to the International Network of Black Soils (INBS) and the FAO report on Black Soils (FAO, 2022a, 2022b), these mineral soils are characterized by dark colors, thick surface horizon, high levels of organic carbon and high natural fertility. The Black Soils cover approximately 725 million hectares worldwide, playing an important role in food production and carbon sequestration. In Brazil, these soils are present in specific environments and they occupy small areas, with great climatic variation and parent materials predominantly of mafic (e.g. basalt or diabase) or limestone rocks or the sediments from their weathering, under relief that vary from flat to strongly wavy. Fitting the definition of Black Soils, the soils identified in this study present a thick surface horizon with a structure varying from granular to angular and subangular blocks with a strong degree of development, high saturation by bases, predominance of calcium and magnesium, and content of organic carbon above 6 g kg<sup>-1</sup>, with a large part of these soils having high activity clays. The profiles are located in four different regions of Brazil, with a wide diversity of phyto physiognomies of the vegetation, including: sub-deciduous and deciduous tropical forest, riparian palm tree (carnauba, *Copernicia prunifera*) forest, Cerrado biome (savanna vegetation from grasses to bushes and low trees), and the more subtropical Pampa biome, with open grasslands. The soils are mainly included in the classes of Vertisols and Mollisols, according to the Soil Taxonomy. In all these environments, the Brazilian Black Soils are highly susceptible to erosion processes, especially when the slopes are higher, and degradation, when used for livestock without proper management or agriculture without conservation practices. Strategies for sustainable management of the tropical Black Soils require appropriate agricultural practices and cultivation systems. These approaches must be complemented by formulation initiatives toward soil education, extension and specific protection policy, ensuring the sustainable use of this vital resource for food security and climate change mitigation.

The black soil region of Northeast China is one of the main black soil belts in the world. It is the main grain producing area in China and has made great contributions to ensuring national food security. In recent decades, the degradation of cultivated land quality such as thin, barren and hard in black soil region has seriously restricted the improvement of grain production capacity. A reasonable and scientific understanding of the black soil resources and taking effective measures to protect and utilize the black soil have become the key to the sustainable development of agriculture. However, the complexity of the geographical location, natural environment, agricultural production, and soil resources in Northeast China has hindered the scientific formulation and smooth implementation of soil protection and utilization policies. In this text, we divided the black soil region into six types: songnen plain region, sanjiang plain region, daxing'an and xiaoxing'anling region, liaohe plain region, changbai mountain-eastern Liaoning region, and western sandy region. The characteristics of geography, climate and soil composition in different types of regions were summarized, respectively. The main problems faced by different types of regions were discussed from the aspects of climate, agricultural production and soil limiting factors. The protection and utilization modes applicable to different types of regions were analyzed and summarized to provide reference for coordinating the contradiction between black soil protection and capacity improvement.

US BLACK SOILS, SOIL SECURITY, AND CURRENT EFFORTS ON MANAGING SOIL CARBON FOR CLIMATE CHANGE MITIGATION

R. HODGES

USDA-NRCS, Lincoln, USA

Black soils—likened to Mollisols of the United States Soil Taxonomy system—while more restrictive in classification, are extensive throughout the contiguous United States. Black soils generally infer fertile soils and are a major contributing factor to soil and food security. The US Department of Agriculture has a suite of research programs intended to supplement and further the soil survey program and region-specific land use recommendations including Dynamic Soil Properties for Soil Health, the Long-Term Agroecosystem Research network, and the USDA Climate Hubs. Comparative examples of black soils between regions demonstrate the importance of agricultural management systems and the effects of these systems on soil carbon. Inherent soil forming factors and site-specific complexity such as historical land use both play powerful roles in understanding the ecological potential of black soils of the United States. Efforts regarding a Soil Carbon Network and the importance of Dynamic Soil Survey will also be discussed.

#### CARBON ACCUMULATION PROCESSES IN NORTHERN PEATLANDS AND BLACK SOILS

Z. YU

Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences, Changchun, CHINA

Peatlands (Histosols, or organic soils)—mostly distributed in the boreal and subarctic regions—contain the largest carbon stock among all terrestrial ecosystems and have the highest soil carbon density. On the other hand, black soils (Mollisols, or Phaeozems and Chernozems)—often developed under grass-dominated vegetation in temperate semi-arid regions—are among the most carbon-rich mineral soils. Here we discuss carbon accumulation processes of both soils types in terms of soil forming factors. We systematically examined the climate spaces of northern peatlands and black soils regions and found that, compared to peatlands, black soils have a narrow range of precipitation. Peatlands are waterlogged peat-accumulating wetland ecosystems often situated on flat terrains, while black soils often distributed on gentle sloping terrains to avoid excess soil moisture and waterlogging. Black soils often formed on unconsolidated parent materials—most commonly eolian loess—to facilitate water infiltration and root penetrations, while impermeable mineral base layers are often favor waterlogging and peat formation. Biomes with abundant grasses seem to be the dominant vegetation favor the formation of deep black soils. Dense grass roots, especially at the subsurface layer, can directly transfer a large amount of organic matter to loess parent materials to form characteristic upper black horizons. Furthermore, frequent wildfires are an important and necessary ecological disturbance to maintain grassland ecosystems by preventing tree colonization, so black carbon could be a significant decay-resistant carbon fraction in some black soils. Both peatlands (with at least 30-cm peat) and black soils (with 25-cm upper black horizons) would require multi-millennial timescales to develop. In summary, low decomposition—through soil organic matter protection associated with waterlogging and anaerobic conditions, cold or freezing temperature, and low substrate decomposability—is key for organic carbon accumulation in peatlands. For black soils, dense and deep grass root penetration in favorable loess parent materials appears to be the key pedogenic process to increase soil carbon content in the mineral horizons, along with black carbon and organic carbon-mineral association protection.

GULLY EROSION IN THE MOLLISOL REGION OF CHINA – A CASE STUDY ON HISTORY, EROSION RATES AND CAUSES

Y. WEN <sup>1</sup>, W. WU <sup>1</sup>, B. ZHANG <sup>2</sup>, H. ZEPP <sup>3</sup>

<sup>1</sup> Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing, CHINA

<sup>2</sup> College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing, Nanjing, CHINA

<sup>3</sup> Institute of Geography, Ruhr University Bochum, Universitätsstr, Bochum, GERMANY

Mollisols are of major importance for food security worldwide but are increasingly degraded by soil erosion. Mollisols in Northeast China have been converted into agricultural use only since the 19th century, but gullies are widely distributed. Gully erosion history, rates, and causes in this region remained unclear. We chose a study area with landforms and land-use history typical for the central Mollisol region of Northeast China to estimate the initiation years and rates of gully erosion from 1968 to 2018 using aerial and satellite imageries. The outlet fan deposits of a large gully system were dated by Cesium-137 (<sup>137</sup>Cs) and artifacts. Local farmers were interviewed to verify the results. Gully volumes were measured by a structure-from-motion technique using photos taken from an unmanned aerial vehicle. Our results showed that gully systems had already appeared on the steep slopes and along unpaved roads in 1968. They had become larger and more complex in 2018 by the upslope retreat of the main gullies and side gully formation. Gully incision started in the 1950s and 1960s when the original grassland and forest were completely converted into arable land. The soil loss from gully erosion ranged from 25.7 to 44.7 Mg yr<sup>-1</sup> ha<sup>-1</sup>. Moreover, we showed that several gullies developed after terracing. Improper terrace design caused runoff concentration along terraces and ridges with mean inclination of 3.8%, which resulted in gully incision due to overtopping of terraces at low spots or due to the uncontrolled release of concentrated flow to adjoining unterraced hillslopes. The same processes are responsible for the persistent gully activity after abandonment and vegetation recovery. Finally, we suggested appropriate countermeasures to stop further soil loss and land degradation on abandoned terraced hillslopes in NE China.

#### PROJECT FOR SUSTAINABLE LOW CARBON CROP AND GRASSLAND MANAGEMENT IN BLACK SOILS OF ARGENTINA

M.A. TABOADA, G.E. PERALTA, C. PASCALE MEDINA, C. LONGA VIRASORO, M. FRAGIO

CARBON GROUP AGRO-CLIMATIC SOLUTIONS, AV. DEL LIBERTADOR 3186 CO 1425, BUENOS AIRES, ARGENTINA

Argentina is one of the countries with larger surface (more than 60 million hectares) covered by black soils in the World. During most of the 20th century black soils of Argentina were managed in a rather extensive manner and with aggressive tillage systems, which caused widespread declines (30 to 60%) in the organic matter content. This work shows how several producers dedicated to extensive agriculture (corn, soybeans, wheat, sunflower, cotton, and other crops), and extensive cattle ranching, mostly cattle and grazing grasslands, pastures, agropastoral, and silvo-pastoral make efforts to reduce GHG emissions through the adoption of better nitrogen fertilization technologies, the intensification of agricultural rotations with greater incorporation of winter crops, nitrogen fixing species and cover crops, and improved grazing management in livestock, which increase carbon stocks and with improvements in digestibility that reduce methane (CH<sub>4</sub>) emissions due to enteric fermentation. The project is expected to mitigate emissions by fostering carbon sequestration in soils, through increasing the area and biomass production of cover crops, increasing the participation of perennials in rotations with annual crops, improving crop rotations with crops with higher residue returns, the application of in-farm generated compost, and increasing grassland and pasture residue returns with improved grazing management techniques. It is estimated that with these improvements, which are not currently widespread even among producers, it will be possible to reduce between 0.5 and 3 tons of CO<sub>2</sub>e/ha/year. This area is expected to reach more than 160 thousand hectares. If this is so, it is expected to mitigate almost 2 million tons CO<sub>2</sub>e at the end of this project. Average emissions reductions or removals of the first ten years is: 61,506 tons of CO<sub>2</sub>e per year. And the average annual mitigation and removal rate is estimated in 602 kilos per hectare per year of CO<sub>2</sub>e for the twenty-year period. This projects shows the agricultural sector of Argentina to be a key to climate change mitigation using nature-based solutions.

#### AFFECTS OF SOIL EROSION-DEPOSITION ON CORN YIELDS IN THE CHINESE MOLLISOL REGION

F. ZHENG, Y. WANG, W. YANG, Z. FENG, J. ZHANG

Northwest A & F University, YANGLING, SHAANXI, CHINA, CHINA

Soil erosion is a major challenge for crop production maintenance and improvement in agricultural regions worldwide. However, quantifying the impacts of soil erosion grade on crop yield is still weak, and how soil deposition affects crop yield is less reported, especially in the Chinese Mollisol Region. Thus, this study quantified soil erosion-deposition rates (SEDRs) at three agricultural catchments in the Chinese Mollisol region using the  $^{137}\text{Cs}$  technique and assessed soil erosion-deposition impacts on corn (*Zea mays* L.) yield. The results showed that SEDRs varied from -5471.7 (deposition) to 9956.0 (erosion)  $\text{t}/(\text{km}^2 \text{ yr}^1)$ . The distributions of both soil erosion and deposition in the three catchments were in coexistence, but soil erosion was dominant. In addition, above 2500  $\text{t}/(\text{km}^2 \text{ yr}^1)$  of soil erosion rates (larger than moderate erosion grades) in the three catchments accounted for 41.0%, indicating that soil erosion was severe. Moreover, corn yields in the three catchments ranged from 1.9 to 14.6 t /ha. Compared with deposited sites, corn yields in eroded sites were 19.2% - 40.6% lower. Furthermore, when soil erosion grade was moderate (soil erosion rates  $> 2500 \text{ t}/(\text{km}^2 \text{ yr}^1)$ ), corn yields were 32.4% lower than those in non-eroded sites. The spatial distribution of corn yield was opposite to that of soil erosion rate at catchment and slope scales. The relationship between corn yields and soil erosion rates had a negative linear relationship ( $p < 0.01$ ), which was validated with acceptable accuracy. And there was a positive linear relationship between corn yields and soil deposition rates without statistical significance ( $p > 0.05$ ). These findings are valuable for assessing how soil erosion-deposition affects crop yields to implement countermeasures for controlling soil erosion and maintaining sustainable agricultural development.

#### LONG-TERM GULLY DYNAMICS OVER CROPLAND IN THE BLACK SOIL AREA OF CHINA BASED ON SYSTEMATIC SAMPLING

Y. ZHANG, K.H. LI, R.Z. YANG, J.B. ZHANG, C. CHEN

School of Soil and Water Conservation, Beijing Forestry University, BEIJING, CHINA

Understanding the large-scale spatial distribution characteristics of gully development dynamics, particularly over long periods, can help to accurately identify gully erosion sensitive areas and so be crucial for targeted gully prevention and rehabilitation efforts. This study aims to investigate the long-term dynamics of classical gully on cropland in the Songnen black soil region, which is the most important commercial grain production area in China, covering an area of 212,000 km<sup>2</sup>. For this purpose, 998 sampling units selected using the systematic sampling method were considered. Based on Corona KH-4B images from 1970 and Google images from 2018, all gullies within each sampling unit were visually interpreted. In the past 50 years, the number of classical gullies on cropland in the Songnen typical black soil region increased by 24.55%, while the average linear density of gullies in the cropland sampling unit decreased by 0.4 km/km<sup>2</sup>. While 50.50% of gullies found in 1970 disappeared from the images of 2018, more gullies formed and were widespread in the east part of the study area characterized with the topography of rolling hills. Affected by human intervention, a widespread process of erosion-infilling cycles and a dynamic equilibrium may exist between the formation and disappearance of classical gullies on cropland. In particular, 81.74% of gullies were found to be active, including newly formed gullies and some long-standing gullies, and the average retreat rate of active long-standing gullies was 3.26 m/yr, indicating the severity of gully erosion and limited effectiveness of efforts made to control gully erosion in the black soil region of China. The findings highlight the need for studies on more effective and targeted measures for gully control and their wide application in order to ensure the sustainable utilization of the valuable black soil resources.

## ORAL PRESENTATIONS

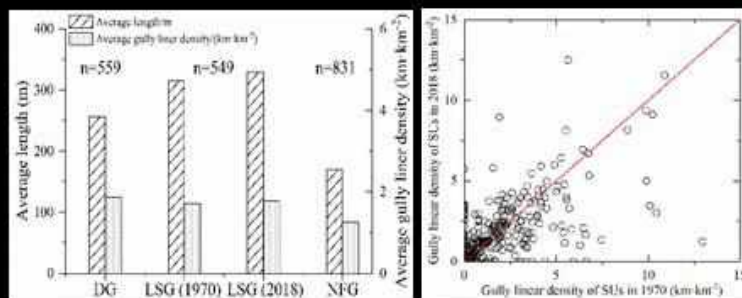

Gully erosion was investigated in the typical black soil area of China.

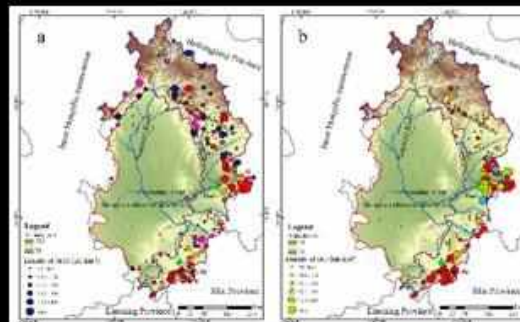

Systematic sampling approach was used together with the interpretation of historical images.

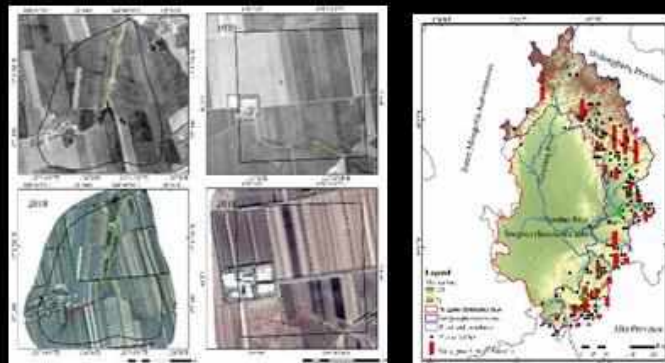

The number of cropland gullies increased but the average gully density decreased from 1970 to 2018.

A dynamic equilibrium was found between the formation and disappearance of gullies on cropland.

The average retreat rate of active long-standing gullies was 3.26 m·yr<sup>-1</sup>.

<sup>4</sup> INDUROT, Campus de Mieres, Universidad de Oviedo, MIERES, SPAIN

Tailor-made artificial soil is a nature-based solution that can be employed to rehabilitate degraded soils, as it enhances their physical, chemical, and biological conditions. Artificial soils are classified as Technosols by the FAO due to containing over 30% anthropogenic materials. In contrast to compost, these Technosols include inorganic materials, mimicking the composition of natural soils.

Due to a lack of data on carbon dioxide removal (CDR) by AS, field trials were conducted with various AS in a dunite mine in NW Spain under the C-SINK project. These soils were formulated to maximize carbon sequestration from CO<sub>2</sub> while fostering plant growth, ensuring a high CDR rate and facilitating the successful growth of forest plantations.

Four different AS formulations were created by blending inorganic and organic wastes. Post-mixing, they were applied to the surface of the dunite mine soil in 300 m<sup>2</sup> plots. Seeds of various plant species were hydroseeded onto the AS surface.

Various soil variables, including soil carbon in different chemical forms, are being monitored over 24 months in the four experimental plots, along with a control and a revegetated plot (business as usual). Unmanned Aerial Vehicle Remote Sensing (UAV-RS) technologies will be utilized to establish correlations between chemical measurements of different organic carbon fractions and multispectral images acquired. The data collected during monitoring will enable the calculation of CDR in AS under field conditions. Additionally, a comprehensive biological evaluation will be undertaken to examine changes in microbiota and soil enzymatic activities. Differences in biodiversity will also be observed by considering both planted and spontaneously growing vegetation.

The present case study is in the framework of the European project C-SINK, which aims to boost large-scale atmospheric CO<sub>2</sub> removal through seven technologies (CDR-T). The purpose of the C-SINK project is to deliver to the EC a complete package of proposals elaborated to support a new or amended European legal/regulatory framework to bring high quality CDRs to the market.

Funded by the European Union. <sup>4</sup> ENAC IIE PERL, EPFL Ecole Polytechnique Fédérale de Lausanne, Lausanne, SWITZERLAND

Urban green spaces supply several ecosystem services (ESS) key to human well-being, especially in the context of increasing extension of cities. Soils in urban areas have multiple functions that are becoming more valued by urban communities. Among them, soils favor carbon storage and climate regulation, biomass provision for food and water flow regulation, and can lower temperatures locally. However, the potential to enhance these ESS via targeted urban soil management remains largely untapped. The main challenge is considering the variability of urban soils due to the inherent heterogeneity of urban environments, intensifying natural soil variability. For instance, due to management practices, urban soils have different degrees of compaction, soil structure alteration, and biological activities. These differences lead to fundamental comprehension gaps in water and heat soil pathways.

Our research aims to study urban soil properties to improve our knowledge of these highly managed environments that influence water and heat regulation. Large herbaceous areas, e.g. urban parks, are ideal research fields, as they allow sampling over large areas away from trees, limiting evapotranspiration effects. The city of Lausanne offers multiple park areas differing in their management and land use. The geographic and geological history of the town provides an excellent opportunity to analyze contrasting environments.

A prospecting campaign is currently made to discriminate and classify the soil types. We identify patterns and variables that help us a better understanding of soil water regulation function: soil depth, structure, porosity, texture, etc. Computer tomography analysis provides better insights into pore networks. The preliminary findings highlight that urban soils exhibit expected heterogeneous features relative to their pedogenesis processes. As a complement, several experiments will quantify the links between infiltration and temperature dynamics to understand urban soils' water and temperature dynamics.

#### PROMOTING CARBON STORAGE AND HEALTH IN URBAN SOILS THROUGH SUSTAINABLE MANAGEMENT PRACTICES

A MOVASSAGH <sup>1</sup>, B BETANCUR CORREDOR <sup>1</sup>, M HAMER <sup>2</sup>

<sup>1</sup> Center for Development Research , ZEF, University of Bonn,, Bonn, GERMANY

<sup>2</sup> International Centre for Sustainable Development, IZNE, Bonn-Rhein-Sieg University of Applied Sciences, Bonn, GERMANY

Sustainable urban soil management is becoming increasingly important because of its critical function in regulating the climate and water and its enormous potential to store soil organic carbon (SOC). Researchers still know little about the amount of urban SOC and the effects of urban soil management practices on soil health and carbon storage. Therefore, we investigated how management practices in urban green spaces affect soil carbon storage and health. The Bonn-Rhein-Sieg region served as the study's area, with a high population density (Rhein-Sieg district: 338.4, Bonn: 520.9 inhabitants/km<sup>2</sup>) in Germany. Managers and owners of urban private (e.g., backyard gardens and allotments) and public green spaces participated in a survey that concerned the practices for the most common vegetation types (e.g., lawn, vegetable, and ornamental). Two hundred forty-eight soil samples (0–20 cm depth) were collected in the autumn and winter of 2022, and their physiochemical and biological characteristics were examined. A multivariate analysis of variance (MANOVA) was carried out to evaluate the effects of various management practices on soil parameters.

According to our findings, public green spaces have an average SOC stock of 94.67 Mg ha<sup>-1</sup>, which is much greater than private ones (home gardens, 67.72 Mg ha<sup>-1</sup> and allotment gardens, 73.15 Mg ha<sup>-1</sup>). When comparing vegetation types, ornamentals (85.05 Mg ha<sup>-1</sup>) and vegetables (91.66 Mg ha<sup>-1</sup>) exhibit higher SOC stock levels than lawns (62.48 Mg ha<sup>-1</sup>). Significant variations in SOC are also observed when comparing the monthly (127.37 Mg ha<sup>-1</sup>) vs. annual (76.88 Mg ha<sup>-1</sup>) fertilization regimens. In the examined urban green spaces, the average SOC stock (85 Mg ha<sup>-1</sup>) was higher than the average SOC stock (47.30 Mg ha<sup>-1</sup>) in Germany's arable soils. The region's greater SOC could result from the types of vegetation and fertilization frequencies, both of which have statistically significant effects (p-value <0.001). Our findings highlight the critical role that soil management plays in influencing urban SOC, particularly in selecting vegetation types and determining fertilization schedules.

Urban soils are extremely heterogenous as they include a variety of anthropogenic and natural materials. Manufactured or constructed soils (MSs) are created using a wide range of materials and are generally referred to as Technosols. MSs can play key roles in providing ecosystem services including carbon (C) sequestration as part of efforts related to the mitigation of climate change. Plant cover drives the development and functioning of MSs influencing soil organic matter turnover due to organic carbon (SOC) quality and stabilization processes. Challenges in defining and measuring different SOC pools has increased interest in sensitive and non-destructive techniques such as Vis-NIR diffuse reflectance spectroscopy (DRS) and scanning electron microscopy with energy dispersive X-ray spectrometer (SEM-EDS). In the development of new models that encompass the anthropogenic influences on ecosystem service provision, these methods can help to highlight the heterogeneity of MSs and incorporate these factors into models related to urban soil management. In this research DRS was used to analyze the soil organic fraction of MSs made of sand and compost (2/3 and 1/3, respectively) planted with different vegetation (bare, sunflower, edible, cover crops, sunflower+edible, sunflower+cover crops, edible+cover crops and all) at different times (at 5, 12, 15 and 21 months since the plots construction) in the frame of the Carbon Sponge project. In addition, particle aggregation, which is important for SOC stabilization processes, was evaluated by SEM-EDS. The DRS reflectance spectra showed clusters based on times and vegetation that converged after the application of the Smoothing Savitzky-Golay algorithm and spectral conversion into absorbance. Surprisingly, in principal component analyses (PCAs) some plant covers were closer to the initial sand suggesting a rapid utilization of the organic resources by soil microbiota. However, the SEM-EDS showed bigger aggregates in the presence of more complex vegetation highlighting diverse plant contribution to soil. These models can help to better clarify the dynamics of C sequestration and improve management and use of MSs in urban areas.

A recent assessment states that 60-70% of soils in Europe are considered unhealthy. To protect this valuable resource, we need to acquire knowledge about it through soil monitoring to assess the soil status and detect soil changes over time.

In Europe, different types of monitoring networks currently exist in parallel. Many EU Member states (MS) developed their own soil information monitoring system (N-SIMS), some being in place for decades. In 2009, to develop a homogeneous dataset for EU, the European Commission extended the periodic Land Use/Land Cover Area Frame Survey (LUCAS) led by EUROSTAT to sample and analyse the main properties of topsoil in EU.

To support European policies, there is a clear need to evaluate soil quality and establish reference values to assess soil health. However, a question remains whether the assessment obtained by using soil properties from both monitoring programs (N-SIMS and LUCAS Soil) are comparable, and what could be the limitations of using either one dataset or the other.

In the context of EJP Soil, a comparison of three soil properties (organic carbon, pH and clay content) has been conducted among 12 different EU countries including BE, DE, DK, EE, ES, FR, DE, HU, IT, NL, PL, SE and SK. In addition, a comparison of two indicators including (i.e. OC/Clay and pH classes) using each programs dataset has been conducted. The results underlined substantial differences in soil properties statistical distributions between N-SIMS and LUCAS Soil in many countries, particularly for woodland and grassland soils, affecting the evaluation of soil quality using indicators. Such differences might be explained by both the monitoring strategy (spatial distribution of sites) and sampling protocols exposes the potential effect data source on European and national policies. Those results advocate for a dialogue between national institutions conducting soil monitoring and LUCAS Soil to harmonize the data and strengthen future soil monitoring to provide reliable data for reaching the objectives of healthy soils.

#### THE IMPLEMENTATION PHASE OF THE NORWEGIAN AGRICULTURAL SOIL MONITORING PROGRAMME

T. GÓMEZ DE LA BÁRCENA, D. KOLBERG, N. HUA LY KOK, R. LÅGBU, G. STRAND, S. SVENDGÅRD-STOKKE

Norwegian Institute for Bioeconomy Research, Ås, NORWAY

In 2022, the Norwegian Agricultural Agency granted the implementation phase of a national soil monitoring programme for Norwegian agricultural land. The aim was to establish the systems and protocols needed to ensure data collection, data management and analyses, develop a strategy for communication and acquire the necessary equipment. The programme will monitor a set of indicators selected to measure the state and development of five main threats to Norwegian agricultural soil: loss of organic matter, soil erosion, soil compaction, soil contamination and loss of soil biodiversity.

Norway has a small share of agricultural land compared to its total land area (approximately 3%, National Land Resource Map, 2022, NIBIO). However, the programme plans a dense sampling grid to ensure sufficient coverage of the heterogeneous Norwegian agricultural soil. The programme will use a square 1x1km grid from which points under agricultural use have been randomly selected. In a cycle of 10 years, more than 800 sites are expected to be visited. Approximately 10% of these sites will be monitored for biodiversity and contamination and this will be done every 5th year to capture the faster dynamics of those indicators. The programme plans to use high-precision positioning systems to ensure that resampling is done at the exact same place, since the relocation of plots has been pointed out as an important source of uncertainty in monitoring programmes. A questionnaire to collect the most relevant information about management practices on the plots has been developed in collaboration with farmers and farmer's associations in Norway. Overall, the set of indicators, field protocols, and analytical methods selected during the implementation phase are closely aligned with that proposed by the Directive for Soil Monitoring and Resilience launched by the European Union in July 2023 (COM(2023)416). The program will continue with further testing during 2024 until the start of its full operational phase.

Soil biodiversity loss is one of the greatest threats in many regions of the world and is likely underestimated due to the lack of data. Although aboveground biodiversity has been promoted and protected for decades, little attention has been given to belowground biodiversity.

As part of the post-2020 Plan of Action of the International Initiative for the Conservation and Sustainable Use of Soil Biodiversity adopted at the 2022 Conference of the Parties to the United Nations Convention on Biological Diversity (CBD COP15), the Food and Agriculture Organization of the United Nations (FAO) was mandated to implement a global soil biodiversity and ecosystem function monitoring framework. The Global Soil Biodiversity Observatory (GLOSOB) aims to provide information to guide evidence-based decision-making by measuring, mapping, and monitoring soil biodiversity in a harmonized way. The outcome will be to provide soil biodiversity insight to conservation and restoration practices for sustainable agriculture.

Soil biodiversity (microflora, microfauna, macrofauna, and biological processes) will be measured, and monitored using standardized methods that complement Essential Biological Variables (EBVs) established by other initiatives (e.g., SoilBON). Here we outline EBVs for GLOSOB and their implementation.

We also lay out a framework for a country-driven adoption of GLOSOB in compliance with the COP15 decision. FAO technical networks will help establish sampling and monitoring efforts where requested and will work to complement and reinforce ongoing or planned soil biodiversity observatories or initiatives. To mainstream soil biodiversity measurements, we recommend they become a standard in the revised FAO Guidelines for soil description as part of national soil surveys and in assessments of agricultural sustainability.

<sup>2</sup> Institut Agro, Rennes, FRANCE

The continuing rise in energy prices is affecting fertilizer prices, and is accompanied by a general reduction in phospho-potassium fertilization of agricultural plots nationwide. In France, since 1990, the Base de Données des Analyses de Terre (BDAT INFOSOL INRAE Orléans) has brought together the results of soil tests of cultivated topsoil carried out throughout mainland France, at the request of farmers, by laboratories approved by the Ministry of Agriculture. This database contains over 3 million phosphorus (P) determinations and an equivalent number of exchangeable potassium (K) and magnesium (Mg) determinations. These data were mobilized as part of a spatio-temporal diagnosis to provide information on the spatio-temporal trends of these three fertility parameters over the period 1990-2020, and to identify the consequences on the availability of these elements for crops.

General trends in the evolution of agricultural soils in mainland France show an increase in pH and Mg content, and a decrease in K, but especially P, content. The spatial distribution of exchangeable P Olsen, K and Mg contents in soils seems to depend mainly on soil characteristics (texture, mineralogical nature of parent materials). The temporal trends observed for Olsen P and exchangeable K, on the other hand, seem to depend on economic factors (rising energy and fertilizer prices), the presence or absence of livestock farming, and recommendations for lower dose calculations as part of a rational fertilization approach.

This work demonstrates the importance of collecting and collating this information, produced in an individual context for plot management, in order to reuse it in a general context and produce results on the statistical distributions of agricultural soil fertility indicators. However, these preliminary results should be treated with caution and should not be used for the fertilization of agricultural plots.

The EU Soil Strategy for 2030 and the Proposal for a Directive on Soil Monitoring and Resilience aim to achieve healthy soils by 2050. This information is currently provided at European level by LUCAS soil survey and nationally through monitoring networks (N-SIMS) developed individually by each member state with different approaches. In this context, integrating data from diverse sources (i.e. LUCAS soil and N-SIMS) is essential.

Under the EJPSOIL programme, twelve countries employed a common methodology to compare their N-SIMS to LUCAS Soil in terms of sampling strategy and representativeness of land use and soil types. This analysis revealed significant disparities in monitoring strategies, including variations in sampling design, monitored land cover, and sampling depth. While most N-SIMS and LUCAS Soil used a stratified random sampling design, some N-SIMS employed a regular grid approach. Sampling depth varied across countries, with some using fixed depth intervals and others opting for soil horizons sampling, while LUCAS Soil sampled topsoil at 0–20 cm depth (0–30cm in LUCAS 2022). Site density was generally higher in N-SIMS than in LUCAS Soil, with some cases exhibiting a difference of one order of magnitude. The significant increase in the number of sites in the LUCAS Soil 2022 campaign partially filled this gap. The spatial distribution of N-SIMS appeared more homogeneous than LUCAS Soil, especially in countries like France and Spain where N-SIMS followed a grid-based system and in regions with extensive mountainous areas systematically excluded by LUCAS Soil. Comparisons of site proportions in different soil types or land cover classes indicated that N-SIMS results were more aligned with the current estimated proportions (calculated by using Corinne Land Cover and WRB, respectively) compared to LUCAS Soil. However, both methods exhibited significant variations from current estimated proportions. This work underscores differences in sampling protocols and representativeness among N-SIMS and between N-SIMS and LUCAS Soil. This is a preparatory work towards the soil properties comparisons among soil monitoring programs.

#### A FRAMEWORK FOR SETTING SOIL HEALTH TARGETS AND THRESHOLDS IN AGRICULTURAL SOILS

A. MATSON <sup>1</sup>, SEE ATTACHED FILE <sup>2</sup>

<sup>1</sup> Wageningen Environmental Research, WAGENINGEN, THE NETHERLANDS

<sup>2</sup> SEE ATTACHED FILE

Soil health is a key concept in worldwide efforts to reverse soil degradation, but to be used as a tool to improve soils, it must be definable at a policy level and quantifiable in some way. Soil indicators can be used to define soil health, and both quantify and monitor the degree to which soils fulfil expected functions. Indicators are assessed using target and/or threshold values, which define achievable levels of the indicators or associated soil functions. However, defining robust targets and thresholds is not a trivial task, as they should account for differences in soil type, climate, land-use, management, and history, among other factors. We assessed (through theory and stakeholder feedback) four approaches to setting targets and thresholds: fixed values based on research, fixed proportions of natural reference values, values based on the existing range (e.g. lower quartile of the observed distribution), and targets based on relative change (e.g. a 20% increase of the indicator's value). Three approaches (not including relative change) were then further explored using case study examples from Denmark, Italy, and France, which highlighted key strengths and weaknesses of each approach. Here, we present a selection of the assessment and case study results, as well as a framework, which facilitates both choosing the most appropriate target/threshold method for a given context and using targets/thresholds to trigger follow-up actions to promote soil health.

High-quality soil data are essential in monitoring changes in soil properties and the impact of sustainable soil management practices. From this perspective, soil laboratories play a key role as these might be considered the originators of soil data from bulk material. Therefore, there is a need to assess the performance of laboratories analyzing soils for what concerns both precision and accuracy. To do so, inter-laboratory proficiency tests (PTs) are organized by various institutes worldwide. However, accessibility to such external quality control exercises is often challenging for laboratories operating in developing countries with limited available resources. Since its establishment in 2017, the Global Soil Laboratory Network (GLOSOLAN), established under the framework of the FAO's Global Soil Partnership (GSP), engaged over a thousand soil laboratories operating in around 170 countries.

To monitor the performance of soil laboratories worldwide and to later suggest actions to reduce the uncertainty of soil laboratory results, GLOSOLAN organized several regional PTs and two global PTs involving 80 participants from 60 countries (in 2019) and 240 participants from 110 countries (in 2022).

All PTs targeted essential soil parameters for optimal plant growth, used as main indicators to assess sustainable soil management practices (FAO-ITPS, 2020). Most of the time, precision was assessed using replicates, while participants results were converted into Z-scores and their performance evaluated based on the standard deviation of the mean value of the Z score for each of the replicates.

Results showed that most of the laboratories worldwide have issues with both accuracy and precision. Therefore, to reduce uncertainty of soil data worldwide and hence increase the efficacy of decisions based on those data, it is essential to raise the awareness on the role of soil laboratories and encourage global investments in training soil laboratory staff and managers. This can be achieved through the collaborative system promoted by GLOSOLAN, which mobilizes support from high performing laboratories to improve the consistency of global soil data.

<sup>4</sup> Department of Agriculture, Food and Environment (DAFE) - University of Pisa, Pisa, ITALY

Although a precise definition and quantification of soil health has not yet been established, there is a general agreement that the soil's ability to provide ecosystem services is closely linked to its state of health. Assessing ecosystem services (ESs) in an integrated manner remains a challenge. Simple indicators, such as those based on a single time-invariant soil parameter like clay content or AWC, are often used as proxies for evaluating ESs. However, these indicators do not fully capture the complexity of the many integrated ecosystem services (ESs) provided by soil.

Furthermore, it is crucial to evaluate the effects of global change on the provision of ESs in agriculture. Therefore, it is important to develop reliable scenarios for resilience, adaptive capacity, and future risks under different climates and landscapes.

We propose an integrated assessment of multiple potential soil-based ecosystem services through the use of process-based modeling. This will simulate water, heat, nutrients, and crop growth in the soil-plant-atmosphere system, according to global climate change scenarios.

The evaluation focuses on the soil's contribution to i) food provision, estimated through biomass; ii) retention and release of nutrients and pollutants, estimated through soil filtering capacity; iii) water regulation, including runoff potential and flood control; iv) water storage in the soil; v) groundwater recharge; and vi) microclimate regulation, measured by total evapotranspiration.

These ESs are combined into integrated indicators of soil health, to immediately obtain comprehensive information on the potential soil health status at specific locations and for global climate change scenarios. Results obtained by using the proposed approach are shown for the Campania Region (Italy) case study, where several land degradation processes (such as the loss of organic matter and/or soil erosion) have been simulated, according to the specific local pedoclimatic conditions.

Soil degradation is a serious side effect of mismanaged agricultural systems, that inevitably compromises soil health. When attempting to reverse degradation in a complex system such as the soil, having indicators of successful restoration suitable for monitoring are important for adaptive management. Soil biological properties potentially offer the most dynamic and sensitive indicators of soil health allowing regular monitoring to provide relatively fast feedback on the consequences of management decisions, both in the short- and long-term. Decision support tools (DST) are becoming increasingly common as a way to assess soil health and functions on-farm. However, soil biological indicators are still under represented in these assessments. The TUDI project aims to address this shortcoming by developing and validating stakeholder-oriented solutions to evaluate soil status at farm level, tailoring the management techniques to local conditions. The TUDI DST has incorporated a set of soil biological indicators which are designed to facilitate a simple, evidence-based monitoring and assessment as well providing tools for on-farm decision making. Monitoring involves visual field and soil observations, as well as soil testing. Soil biological indicators are grouped into six categories: soil management, surface cover, root system, soil biodiversity, soil tests and additional information. These are then allocated a numerical score which indicates the impact of indicator inputs on soil biology. The results are reported with traffic light scorecards which indicates whether the soil system is in very poor, poor, neutral, good or very good health status. Recommendations to facilitate decision making on soil management are provided by each, above mentioned six categories. With this tool TUDI aims to facilitate the uptake of soil healing strategies in three major agricultural systems and farm typologies across Europe, China and New Zealand.

#### AGROECOLOGICAL TRANSITION OF OIL PALM CULTIVATION IN THE TROPICS: IMPORTANCE OF SOIL HEALTH MANAGEMENT TO ACHIEVE HIGH YIELD.

J. CALIMAN, E. LUPITASARI, P. WAHYUNINGSIH, SUHARDI, PUJIANTO, P. DANISWARAPUTRI, K. SUDHARTA

SMART Research Institute, Pekanbaru, INDONESIA

Oil palm cultivation is a key component of agriculture in most tropical countries. It involves millions of farmers in the 3 continents of Southeast Asia, Africa, and South America, as well as large plantation companies, often in an integrated system organized by governments.

Soil health is a major objective of agroecological approach for the transformation of agriculture. While soil health status and importance are well identified and documented in temperate agriculture, relative few studies and initiatives for transformation have been developed in tropical agriculture, especially on an "industrial" crop such as the oil palm, which carries a significant level of controversy due to its recent development, often on natural ecosystems.

Here we report the results of a large preliminary study implemented in oil palm plantations in Indonesia, aiming at identifying the components and variables for the characterization of soil health as the basis for the transformation of oil palm cultivation.

The importance of soil health management is demonstrated, and the variables for the assessment of soil health status, and subsequently the required agronomic recommendations for improvement are identified. Half of these variables measured (from more than 20) shows a significant relation with the yield of the palms, including most variables representing the biological and physical components of soil health status, together with agricultural practices (especially biomass recycling and soil natural vegetation cover) driving the level of these variables. On the other hand, most variables related to the chemical component of soil health do not show significant positive impact, most probably because they have been transformed by the fertilizer management approach adopted by farmers.

These results have been used to propose best agricultural practices for the agroecological transition of large areas of the oil palm landscape, including both small farmers and large plantations, with conservation agriculture approach recommended in area showing good soil health status, while the regenerative agriculture approach is recommended for these areas showing some level of soil degradation.

#### MATCHING SOIL PERFORMANCE INDICATORS TO AUSTRALIAN FARMING SYSTEMS

N. ROBINSON, A. CHADHA, A. OLLERENSHAW

Centre for eResearch and Digital Innovation, Federation University Australia, Mount Helen, AUSTRALIA

Soil indicators in the form of tests, assessments and observations provide vital measures of soil performance and important information to farmers about soil health. Use of soil indicators within agriculture is widespread, however less is known about the factors that influence the choice of indicators for Australian farms that support their farming practices. Research was undertaken to investigate (i) what tests and assessments are being used in grains, sheep and cattle enterprises, (ii) how frequently these tests and assessments are conducted, (iii) why are these tests and assessments chosen, and (iv) what factors influence their soil indicator choices? A survey was distributed to 10 farmer groups across Australia with 228 surveys being collected from farmers, advisors and researchers. The data revealed that plant growth or yield was the highest used observation by the grains (95.7%), cattle (85.2%), and sheep (89.1%) enterprises, followed by field walk or drive. For chemical testing, available phosphorus was widely used across grains (76.8%), cattle (76.5%) and sheep (81.5%) enterprises. Out of the physical tests, stability of aggregates in water was most frequently used test by grains (53.7%), cattle (50.6%), and sheep (53.3%) enterprises. Root health/rooting depth is the most widely used of all the biological tests presented. Over half of the survey respondents' choice of soil tests was based on the relevance to their production decisions and farming enterprise and for their ease of sampling, observation and assessment. Respondents identified field days and farms walks as important sources of information that influenced their soil indicator choices. The research findings indicate that no single soil property or group of properties can universally indicate soil performance across the variety of Australian farming systems. This study indicates that soil indicators must be matched to their purpose, in the context of when and where they are measured and how the indicator value relates to a baseline and the threshold values of the measure for that purpose.

#### ON-FARM ASSESSMENTS OF SOIL HEALTH AND SOIL FUNCTIONS IN SOUTHEAST NORWAY

F. BØE<sup>1</sup>, J. STOLTE<sup>2</sup>, L. VAN SCHAİK<sup>1</sup>, C. RITSEMA<sup>1</sup>

<sup>1</sup> Wageningen University & Research, Wageningen, THE NETHERLANDS

<sup>2</sup> Norwegian Institute of Bioeconomy Research, Ås, NORWAY

Soil health is defined as “the ability of the soil to sustain the productivity, diversity, and environmental services of terrestrial ecosystems”. Practices entailing minimum soil disturbance, soil cover and crop diversification have been highlighted for improving soil health, and thereby improving soil functions and the delivery of ecosystem services. However, evidence on the effect of these practices, such as conservation agriculture, on soil health, is limited in Norway, mainly due to unfavourable conditions for practicing no-till and establishing cover crops in cold climate conditions. This paper presents results on the effects of long-term conservation practices compared to conventional farming on soil health and soil functions on loam soils in Southeast (SE) Norway. We measured physical, chemical and biological soil indicators on two neighbouring farms, one with no-till, diverse crop rotation and cover crops (Conservation) and one with harrowing and ploughing and low crop rotation (Conventional). Soil indicators measured included aggregate stability, bulk density, cohesion, soil roughness, saturated hydraulic conductivity (physical), total organic carbon (TOC), total nitrogen (TN), C/N-ratio and pH (chemical), and permanganate-oxidizable carbon (POXC), earthworm count, and plant coverage (biological). Results show higher aggregate stability (%) in the conservation field ( $91.3 \pm 4.2$ ) compared to the conventional field ( $56.9 \pm 6.9$ ). Higher TOC was found in the 0-15 cm depth in the field with conservation practice compared to the conventional field, while the opposite trend was measured for the 15-30 cm depth. POXC was higher in the conservation field compared to the conventional field for both soil depths. Significantly different ( $p < 0.001$ ) earthworm count was found in the field with conservation practice ( $24.7 \pm 6.4$ ) compared to the conventional field ( $6.0 \pm 3.2$ ). Finally, we compare the effects of the two farming practices on different soil functions expressed by the measured soil indicators.

Integrating soil health considerations into the activities of soil stakeholders is a requirement for sustainable soil management. In addition to regulations and incentives, pertinent, reliable and scalable information on drivers, states and trends in soil health are needed. For this, Monitoring, Reporting and Verification (MRV) frameworks must be developed at various scales and based on 1) standardized, sound and economic sampling designs for assessing soil health indicators (Monitoring), 2) a reproducible and transparent way to report results (Reporting) and 3) a reliable verification process conducted by an independent structure (Verification).

So far, MRV frameworks for soil management have mainly been applied in the context of carbon sequestration. Expanding such frameworks to multiple soil indicators and the far more complex issue of soil health is a major challenge. They must account for the requirements of different land uses and of different spatial scales. To achieve trust and widespread implementation by diverse stakeholder groups, they need to reconcile scientific robustness with economic and logistic limitations of real-life applications.

The Horizon Europe project BENCHMARKS funded under the Soil Mission, started in 2023 and will run for five years. Its objectives are 1) to test and define indicators for soil health and 2) support their implementation with different tools, across various scales and land uses and by intensive stakeholder involvement and co-design. Among these tools, MRV frameworks will be defined from 2024. The involved stakeholders will work in connection with different land uses (forests, agriculture or/and urban areas) and at different spatial scales (local, national, European or/and Global scale). Numerous outcomes are possible. For example, the final designed MRV could be integrated in the product value-chain of a company, in certification labels or in large-scale soil monitoring, supported by European and national institutions.

In this communication, we will present an analysis of the challenges related to setting up MRV frameworks for soil health and the early results for MRV co-design with the stakeholders.

#### IMPROVING BASELINE MAPPING OF SOIL ORGANIC CARBON USING LOCAL GEOSTATISTICS: AN APPLICATION AT REGIONAL SCALE IN TUSCANY (ITALY)

G. BUTTAFUOCO<sup>1</sup>, L. GARDIN<sup>2</sup>, R. LORENZETTI<sup>2</sup>, F. UNGARO<sup>2</sup>

The status and change of soil organic carbon (SOC) concentration are fundamental for assessing soil health, its functionality and contribution to climate regulation. Organic matter decline is one of eight soil threats identified in the EU Thematic Strategy for Soil Protection (EU 2006). The indicator for assessing SOC loss threat is based on SOC change but measuring any change in SOC content requires establishing a SOC baseline. Geostatistical methods are commonly used both for predicting SOC concentrations at unsampled locations and their mapping. However, most geostatistical algorithms rely on variograms, which are usually assumed to remain unchanged through the area of interest. Therefore, it is assumed the stationarity of data and its spatial structure (variogram) over this area. That is a strong assumption, which may not hold. Local geostatistics (LGS) approach allows the local optimization of geostatistical parameters involved in variogram-based models ensuring a better adequacy between the geostatistical model and the data. Particularly, LGS considers locally varying parameters to address non stationarity and local anisotropies and allows to focus on local particularities. The study was aimed at improving baseline mapping of soil organic carbon (0.30 m) using local geostatistics at regional scale in Tuscany (Italy). It was developed within the SERENA project (European Joint Programme on Agricultural Soil Management, EJP SOIL, European Union's Horizon 2020 R&I programme, grant agreement N° 862695) using the SOC dataset of Tuscany Region presented in Gardin et al (2021). To improve the estimation of SOC concentrations by kriging, the elevation, being exhaustively available over the whole area of the Tuscany region, was used as an external drift. To assess the improvement of SOC prediction, the dataset was split into calculation and validation sets. The performance of the LGS approach was assessed by error statistics and compared to the results obtained using a global variogram model. Finally, the baseline map of SOC was complemented by the assessment of the spatial uncertainty using sequential Gaussian simulation.

Ecosystem services are the direct and indirect contributions of an ecosystem to human well-being. Most ecosystem services required to maintain terrestrial environmental and ecological systems arise from the soil, known as soil-based ecosystem services (SESs). SESs are directly and quantifiably controlled or provided by soils and their chemical, physical and biological properties, processes and functions. SESs do not occur separately in the environment, but simultaneously. They should thus be evaluated together as SESs bundles. In addition, these services are threatened by global changes, such as climate change and changes in land use, which will affect their provision. This work is aimed at defining SESs bundles at the European Union (EU) level, and at evaluating the effect of climate and land use changes on their evolution by 2050. The SESs assessed are hydrological control (HC), soil erosion control (SEC), greenhouse gas and climate regulation (GHG) and primary biomass production (PBP). To assess HC, the digital soil mapping approach was used. SEC was quantified through the Revised Universal Soil Loss Equation (RUSLE). For GHG and PBP, dynamic global vegetation models (DGVMs) produced by UK Earth system models (UKESM) were used. The impacts of climate change were assessed using two Shared Socioeconomic Pathways (SSP1-2.6: sustainable scenario and SSP5-8.5: high-emission scenario with significant climate impacts). Concerning land use change, we used the projections provided by the LUISA (Land Use-based Integrated Sustainability Assessment) modeling platform. The assessment offers a comprehensive analysis of the spatial distribution and projections for the SESs bundles in the current state and by 2050. Clustering methods, specifically k-means, were employed to identify SESs bundles at EU scale. The proposed approach allowed us to identify hotspots with high or low provisions of SESs and how they will be evolved by 2050 under the pressure of climate and land use change. Moreover, it could provide guidance for sustainable agriculture in the framework of the EU Green Deal and the Soil Strategy for 2050.

#### SUSTAINABILITY OF SOIL QUALITY INDICATORS OF EPICALCIC CHERNOZEM UNDER SOIL EROSION CONTROL TECHNOLOGIES

G. KUNCHEVA<sup>1</sup>, V. KOLCHAKOV<sup>1</sup>, J. PERFANOVA<sup>1</sup>, T. PAPARKOVA<sup>1</sup>, G. GYNCEV<sup>2</sup>, M. KERCHEVA<sup>1</sup>

Water erosion and loss of organic matter are interrelated soil degradation processes that lead to a decline of soil fertility on sloping arable lands. A three years' field experiment with wheat and maize in rotation was conducted on Epicalcic Chernozem on slope of 5°, including conventional tillage along the slope (T0), conventional contour tillage (T1) and minimum tillage (T2), with the inclusion of a cover crop. The aim of the study was to assess the influence of constant application of these technologies on soil quality indicators. The soil microbial, chemical and physical properties were measured at two depths in April and October each year. A higher amount of total organic carbon (TOC) was reported in T1 and T2 in the second and third year. The soil microbial biomass carbon content increased in T2 in the second year (by 0.67 mg 100 g<sup>-1</sup> under wheat) and in the third year (by 3.74 mg 100g<sup>-1</sup> and 4.80 mg 100 g<sup>-1</sup> under wheat and maize, correspondingly). An increase in the activity of peroxidase and polyphenol oxidase was reported even in the first year, while the activity of protease, urease, alkaline phosphatase and β glucosidase increased more significantly in the third year. Under T2, the available forms of macroelements and electrical conductivity slightly decreased in some periods, due to including of cover crop. The water stability of soil aggregates had a well pronounced seasonal dynamic. An increase of the plant available capacity (PAWC) under T2 was observed in 0-10 cm soil layer in April under maize. In autumn, the erosion control technologies prevented the subsoil compaction and decrease of PAWC. In conclusion, the applied erosion control technologies lead to a stable increase in enzyme activity, microbial biomass and TOC and soil physical parameters compared to the conventional crop cultivation along the slope.

IS THE ORGANIC CARBON-TO-CLAY RATIO A RELIABLE INDICATOR OF SOIL HEALTH?

T. TÖRMÄNEN, A. LEHTONEN, L. MENICHETTI, E. MARTINEZ-GARCIA, R. MÄKIPÄÄ

NATURAL RESOURCES INSTITUTE FINLAND, HELSINKI, FINLAND

Soil health refers to the ability of the soil to sustain the productivity, diversity, and environmental services of terrestrial ecosystems. The European Union is targeting to improve soil health and soil-based ecosystem services, and as part of the proposed Soil Monitoring Law, the European Commission recommends the monitoring of the soil carbon loss indicator among other soil health indicators.

This main objective of this study was to evaluate the feasibility of the proposed soil carbon loss indicator by assessing its performance using the EU-wide 2009 LUCAS soil survey data in combination with other datasets for soil class, climate zone, and mineral soil carbon stock changes. The proposed indicator for soil carbon loss is soil SOC:Clay ratio, with a threshold value of 1:13. The results of this study are also compared with the carbon stock changes reported by countries to the climate convention (UNFCCC).

Our results reveal that the variation in SOC and clay content at European scale exceeds that of the data used to develop the proposed soil carbon loss indicator. We also found that the variation in the SOC content was influenced not only by clay content but also by climate and land-use reflecting carbon input levels. Therefore, the defined threshold value 1:13 of SOC:clay ratio is inadequate for detecting degraded soils if the SOC and clay content are beyond the conditions used to establish the criteria. Furthermore, major discrepancies were observed between the soil carbon stock changes reported by the national GHG inventories and the proportions of degraded soils identified by using the soil carbon loss indicator. We conclude that using a single indicator such as SOC:Clay ratio with one threshold value for all soils across various land uses, management practices, and climatic conditions, as defined by the European Commission for the Soil Monitoring Law, is inappropriate for monitoring soil carbon loss.

#### DIFFERENTIAL EFFECTS OF AGRICULTURAL INTENSIFICATION ON THE DIVERSITY OF PROKARYOTES, FUNGI, AND PROTISTS ACROSS AGRICULTURAL SOILS IN QUÉBEC, CANADA.

<sup>1</sup> CHU de Québec - Université Laval, Québec, CANADA

<sup>2</sup> IRDA, Québec, CANADA

The intensification of agriculture has negative effects on soil health and crop productivity. As a result, chemical inputs and soil tillage are being used more, which further impacts soil biodiversity and soil health. Although new sustainable practices are emerging, it is still difficult to evaluate their short-term impact on soil functions and soil health. To develop new biological indicators that can respond to management practices, we need to increase our knowledge of the effects of different cropping systems on the complete range of microbial groups present in agricultural soils. Furthermore, we need to evaluate the effects of environmental co-variables on soil microbial diversity and their impact on soil-plant interactions.

A total of 1700 soil samples were collected to represent the diversity of agricultural soils in the Province of Québec, Canada. For each soil series, four cultivated sites and two control sites were studied to determine the soil microbial diversity. A range of physico-chemical characteristics was also analyzed, along with pedological description, tillage, fertilization management, and cropping systems histories. We evaluated the diversity of prokaryotes, fungi, and protista in two soil layers using MiSeq amplicon sequencing. The diversity was assessed with the Shannon's index and Aitchison distance. Differential analysis was performed with ANCOM-BC to assess the impact of agricultural intensification on microbial diversity.

Soil's microorganism composition is shaped by agricultural intensification and parent soil material. Bacteria diversity is mainly affected by parent material and pH level, while fungi and Protista diversity are more impacted by crop system intensification. Control and grassland sites have lower bacteria Shannon index values, but those for fungi are higher. There is no discernible impact on bacteria to fungi ratio.

Studying microbial diversity globally is important to better understand the impact of agricultural management on soil and plant interactions. However, integrating microbial groups and microbiome data into new models remains challenging to accurately predict soil health and the effects of agricultural management practices.

<sup>2</sup> National Biodiversity Future Center (NBFC), Palermo, ITALY

<sup>3</sup> CNR, Research Institute on Terrestrial Ecosystems (IRET), Firenze, ITALY

The Italian National Recovery and Resilience Plan (NRRP), funded by the European Commission-Next Generation Europe, aims to create a more equitable, sustainable, and inclusive society in Italy. For this purpose, NRRP has supported the creation of the National Biodiversity Future Centre (NBFC) for promoting the sustainable management of Italian biodiversity. One of the main goals of NBFC is to improve the application of Nature-Based Solutions in anthropized and natural areas to mitigate global climate changes and to support ecosystem services.

In this work, some of the research activities carried out by NBFC are presented: 1) design, application, and management of restoration actions for degraded land recovery; 2) evaluation of the impact of urban forestry on supporting and regulating ecosystem services in urban areas.

For the natural areas, the application of restoration actions through different forest practices is currently being tested in areas degraded and subjected to abiotic disturbances. The efficacy of such environmental restoration is deepened in post-fire sites of Monte Pisano (Italy), and riparian sites frequently subjected to flooding events. The main soil indicators are monitored to detect the effect of restoration activities on soil quality, with a focus on microbial nutrient limitation and soil nutrient cycles.

In urban areas, the capacity and efficiency of urban forestry in providing ecosystem services, including air pollutant mitigation and soil carbon sequestration, have been studied. For this purpose, in several Italian cities characterized by different climatic conditions and urbanization degree (e.g., Torino, Milano, Firenze, Pisa, Livorno, Roma, Napoli, and Campobasso), sampling areas have been selected based on green cover and fragmentation. Soil enzyme activities, soil microbiome, soil and plant isotope signature, plant functional traits, and air quality were investigated to identify specific indicators of the soil-plant-atmosphere system.

The NBCF activities will provide strategies and guidelines as well as databases and tools for the designing of NBS aimed at promoting biodiversity, preserving and recovering soil health and resilience in urban and natural areas.

#### INSIGHTS INTO MACHINE LEARNING-BASED PREDICTIVE MODEL OF RICE GRAIN ARSENIC ACCUMULATION: INTERPLAY OF RICE CULTIVATION SYSTEMS AND SOIL ENVIRONMENTAL FACTORS

S. MAJUMDER<sup>1</sup>, P. BANIK<sup>2</sup>

<sup>1</sup> School of Agricultural Sciences and Technology, RIMT University, Mandi Gobindgarh, INDIA

<sup>2</sup> Agricultural and Ecological Research Unit, Indian Statistical Institute, Kolkata, INDIA

Behaviour of Arsenic (As) in paddy soils is of great interest, where As transfer to rice significantly impacts increasing As levels in rice grain. The study explores an efficient predictive model for rice grain As accumulation using ensemble machine learning algorithms. We collected seasonal flooded paddy-field soil samples from thirty locations in a rice-growing district of West Bengal (India). The field plots were categorized into monsoon and post-monsoon cultivated rice-growing conditions. The monsoon rice is grown under rainfed cultivation, while the post-monsoon season requires intense use of As-contaminated irrigation water. From the field collecting data, the model validation was performed by measuring soil characteristics, which include pH, organic carbon, total concentrations of As, Zn, Cu, Fe, Mn, Ni, geochemical fractions of As (exchangeable and amorphous iron oxide bound As), considered as predictor variables. The model accuracy was determined by using ten-fold cross-validation. Multivariate prediction models show that the random forest performed well in predicting rice grain As concentrations (RMSE=11.98) over the generalized linear model (RMSE=12.70). We further converted grain As into categorical (rainfed and irrigated) for binary predictive classification and compared the accuracy of random forest and logistic regression based on sensitivity, specificity, F1 scores. Random forest showed better performance matrices where exchangeable As was determined to be the most important variable. From the cut-off accuracy plot, the limiting values of 162  $\mu\text{g kg}^{-1}$  and 1690  $\mu\text{g kg}^{-1}$  were estimated for exchangeable and amorphous iron oxide bound As in soil, respectively, under the study conditions. In addition, the pollution status in collected soils was interpreted by the various geochemical indices, which demonstrate that the soils of the study sites are moderately polluted. This study helps to propose careful soil management practices that can minimize rice As transfer and proves the usefulness of machine learning model validation with a better understanding of soil environmental quality and biogeochemical health.

Aboveground environment and soil diversity can be used to understand belowground resource use efficiency of the soil biota and organic matter persistence in soil. This contribution reports preliminary results of a study settled in Pianosa Island (Tyrrhenian Sea), with an extension of 10.3 km<sup>2</sup>, belonging to the Tuscan Archipelago National Park (Italy). Thanks to its geographical position, coupled with its peculiar history, Pianosa can be considered an excellent natural open-air laboratory for studying soil functions under typical Mediterranean climatic conditions. In fact, Pianosa has been cultivated since long time, and had been an agricultural penal colony for more than one century. Since the beginning of the 90's, the agricultural fields were abandoned, and thereafter, the natural vegetation started expanding, without anthropic influences. This allows studying the effect (impact) on all the environmental compartments of a natural recolonization process in past agricultural soils. Four main ecosystems were identified: abandoned agriculture fields, abandoned pastures, natural Mediterranean macchia and planted coniferous forests. These ecosystems were studied in terms of environmental (main physiographic and vegetation cover aspects) and pedological characterization, considering several soil parameters (chemical, physical and functional) and the soil mesofauna diversity. The aim of this study was to evaluate which soil properties, aboveground aspects, or different past utilizations, have mainly affected soil activity and carbon mineralization, under the ongoing natural process of recolonization in Mediterranean condition, where the main driving force is climate.

#### ENVIRONMENTAL RESTORATION THROUGH SOIL CONSERVATION. A CASE STUDY OF MONTE GIBRALFARO (MALAGA, SPAIN)

C. MORENO ALARCÓN<sup>1</sup>, J.A. SILLERO MEDINA<sup>1,2</sup>, J.D. RUIZ SINOGA<sup>1</sup>

<sup>1</sup> HABITAT, TERRITORY AND DIGITALIZATION UNIVERSITY INSTITUTE, Málaga, SPAIN

<sup>2</sup> COMPLUTENSE UNIVERSITY OF MADRID, Madrid, SPAIN

Soil conservation in natural areas within urban settings is essential to ensure environmental sustainability. These spaces act as green lungs, providing crucial ecosystem services such as carbon sequestration, water regulation and habitats for biodiversity. Proper land management in these urban areas contributes to air quality, human health and resilience to extreme weather events, promoting a balance between urban development and environmental preservation. In a context of climate change, especially in highly vulnerable areas such as the Mediterranean, land degradation processes are one of the main threats. Therefore, the development of sustainable strategies for the evaluation and characterisation of soils, as well as the conservation, restoration and renaturalisation of these spaces is a key factor in land management. Under these premises, the current work focuses on an urban forest area in the city of Malaga (Spain) - Monte Gibralfaro - characterised by low biodiversity and a lack of territorial connection with the natural matrix, which makes it more vulnerable to the effects of climate change. The objectives of this research are: (i) to determine soil erosion rates using the RUSLE model; (ii) to estimate SOC stocks as an indicator of soil health; (iii) to evaluate the dynamics of vegetation cover in recent years using spatial remote sensing techniques; and (iv) to promote strategies and actions for soil conservation and the improvement of ecosystem services. In short, the work aims to provide a general characterisation and diagnosis of the state of soil health and, subsequently, to design different actions focused on the restoration of soils as an essential component of environmental dynamics.

<sup>3</sup> University of Perugia, Department of Agricultural, Food and Environmental Sciences, Perugia, ITALY

This study aimed at understand the role of climate and plant species on soil organic carbon (SOC) decomposition. Along an altitudinal transect ranging from 500 to 1000 m a.s.l. on a limestone massif in central Italy, we selected two adjacent toposequences, one covered by pine forests and the other by oak (500 m) and beech (1000 m) forests. Twice a month for one year, soil samples (A horizon) were collected and analysed, and CO<sub>2</sub> efflux and forest floor thickness were measured. SOC content did not differ between the deciduous forests, while it showed larger content at 1000 than at 500 m for the pine forests. The fact that SOC content at both altitudes was significantly different between deciduous and pine forests indicated the importance of the quality of the plant residue for SOC decomposition. Indeed, the increase of  $\delta^{13}C$  in spring and summer for the deciduous forest at 500 m and the lack of seasonal changes of the isotopic signatures for both forests at 1000 m a.s.l., would indicate that temperature most affects SOC decomposition when the substrates are easily degradable. The highest WEOC content observed for all forests in winter season can be ascribed to the lowest C mineralization by soil microbial community (supported also by the lowest CO<sub>2</sub> efflux). This fact, alongside with the similar seasonal trends of the CO<sub>2</sub> efflux recorded in all forests, confirmed the role of temperature on the mineralization processes. The influence of the quality of the plant residue on SOC mineralization was highlighted during the spring and summer seasons, when higher temperatures occurred. Unlike the mineral layer, the forest floor seemed to be mostly affected by temperature, showing the lowest thickness in the warmest month in all forests. Finally, in the investigated temperate forest soils, temperature would be the most important driver in SOC dynamics, although at lower elevation and higher temperature the quality of plant residues could affect the mineralisation processes.

#### BIOCHAR BOOSTED HIGH OLEIC PEANUT PRODUCTION WITH ENHANCED ROOT DEVELOPMENT AND BIOLOGICAL N FIXATION BY DIAZOTROPHS IN A SAND-LOAMY PRIMISOL

C. LIU <sup>1</sup>, G. PAN <sup>2</sup>

<sup>1</sup> Zhejiang University of Science and Technology, Hangzhou, CHINA

<sup>2</sup> Nanjing Agricultural University, Nanjing, CHINA

Peanut yield and quality are severely threatened by climate change and soil degradation. How biochar technology could help to tackle this challenge is unanswered though biochar is known to improve soil microbial community and plant N supply. A field study with oil peanut in a sand-loamy Primisol receiving organic amendment at 20 Mg ha<sup>-1</sup> in 2021. The treatments included amendment of biochar respectively from poultry manure (PB), rice husk (RB) and maize residue (MB) as well as manure compost (OM) amendment, compared to no organic amendment (CK). In 2022, the 2nd year following amendment, samples of bulk topsoil, rooted soil and plants were collected at peanut harvest. Soil quality, peanut growth traits and microbial community with nifH gene abundance and biological N fixation (BNF) rate were analyzed. Compared to CK, the OM treatment increased peanut kernel yield by 8% but unchanged the kernel quality regarded with oil production. However, treatments of PB and MB increased (both by 10%) while that of RB unchanged the kernel yield. Moreover, all biochar amendments significantly (by 10-25%) improved oilseed quality, particularly with the proportion of oleic acid increased up to 70%. Similarly, OM amendment slightly decreased but all biochar treatments significantly and strongly (by over 80%) increased peanut root development. Furthermore, nodule number and fresh weight per plant as well as the nifH gene abundance of rooted soil were all unchanged under OM and PB treatments but significantly enhanced under RB and MB treatments, compared to CK. Relevantly, all biochar amendments but not OM treatment increased the biological N-fixation rate and the activity of N-acetyl-glucosaminidase. These changes were linked to soil aggregation, moisture retention and P availability affected by the biochars varying in physical and chemical properties. Overall, crop residue biochar boosted peanut yield and quality potentially through the improved root development, diazotrophs community and biological N fixation in line with soil nutrient supply.

Wildfires are natural in Mediterranean forest ecosystems, but fire regimes changed due to LULUC. Salvage logging is used as emergency tool to restore ecosystem functions in the short-term, but its ecological implications are misunderstood. To improve ecosystem resilience, we propose tools for adaptive management in the Mediterranean basin. Soil provides ecosystem services and is an essential component of the environment as result of a complex set of interacting processes, such as those in the plant-soil interphase. Inappropriate management could induce soil degradation and the reduction of soil functions.

In July 2017, a wildfire affected 3,200 hectares (YESTE2017) in SE Spain and six months after (winter 2018), salvage logging was carried out. One and two years after fire (spring 2018, 2019), we conducted an experimental study to monitor soil dynamics depending on the soil burn severity (SBS): unburnt mature, low SBS, high SBS and high SBS with salvage logging.

The ecosystem dynamics were related to the habitat type 9540 (Directive 92/43/EEC, Mediterranean pine forests with endemic Mesogean pines) focused on *Pinus halepensis* Mill. and *Pinus pinaster* Aiton. We set up 72 circular plots (9 plots for 4 SBS and 2 species) to collect soil samples (0-3 cm depth) to analyze enzymatic activity, soil organic matter content (SOM) and thermal properties and calculate the vegetation indices (linear transect method) to evaluate the effect of SBS and salvage logging.

We found differences in the reproductive strategies and biological soil enzymatic activities (phosphatase and glucosidase) in post-fire natural regeneration. The high SBS increased the pyrorecalcitrance of SOM increasing the impact of the fire, showing the highest values in salvage logging. The changes in soil-plant interphase pointed to highlight burn severity and postfire treatment as negative effects.

To improve ecosystem management and maintaining soil health (adaptive management), the salvage logging should be avoided, mainly in high burn severity areas, to prevent reduction of the biological soil quality, and improve the resilience of vulnerable ecosystems.

#### CYANOBACTERIA INOCULATION AND SEWAGE SLUDGE AS SYNERGISTIC STRATEGIES FOR DRYLAND RESTORATION

L. MAGGIOLI<sup>1</sup>, S. CHAMIZO<sup>2</sup>, R. ROMAN<sup>1,3</sup>, Y. CANTON<sup>1</sup>

Drylands, covering more than 40% of the Earth's surface, are highly susceptible to climate variations and human activities, which have led to the degradation of 25-35% of these regions. Since the recovery of ecosystems may need a long time, accelerating the process through restoration activities becomes essential. Traditional restoration efforts often produce unsatisfactory results in drylands partly because they primarily focus on reintroducing vegetation, neglecting other ecosystem components and the importance of vegetation spatial distribution, which often consists of plant patches and biocrust in open areas among plants. Recently, biocrust-forming cyanobacteria have shown promising results as restoration agents in laboratory experiments, but few field studies are available, and many of them demonstrate limited success. On the other hand, sewage sludge (SS) has gained widespread recognition as a soil amendment due to its abundant reserves of organic matter and essential nutrients.

The objective of the present study is to combine these two strategies in an outdoor experiment to determine the optimal dose of SS for improving the effectiveness of cyanobacteria inoculation. This enhanced strategy aims to be applied in subsequent small-scale restoration actions alongside the introduction of native vegetation.

Our findings revealed increased cyanobacteria growth in soil amended with the lowest SS concentration (5 t/ha, at a depth of 2 cm), while at higher SS concentrations, inoculum growth decreased, attributed to competition with the indigenous SS bacterial community. Additionally, SS amendment significantly increased soil organic carbon gain, and the content of tightly-bound exopolysaccharides while cyanobacteria inoculation notably improved soil surface stability, reducing wind erodibility.

In summary, the combined approach of cyanobacteria inoculation and the application of the optimal SS dose emerges as an effective strategy for enhancing carbon acquisition and surface stability in degraded dryland soils.

**SOIL SHAPES THE HABITATS OF TUBER SPP SPECIES (TRUE TRUFFLES). ESTABLISHED KNOWLEDGE AND CHALLENGES IN HABITAT MANAGEMENT: WHEN SUSTAINABILITY MEETS MULTIDISCIPLINARITY.**

G. BRAGATO

CREA, Gorizia, ITALY

Research on the five main true truffle species (genus *Tuber*) of economic interest has consolidated knowledge on their habitats, which require the presence of a symbiont tree and a neutral to sub-alkaline soil with a sufficiently high content of exchangeable calcium. Given these requirements as mandatory, the soil structure has proven to be the key to truffle habitats, both in terms of aggregation - single-grained, granular or small sub-angular blocky - and porosity - more than 10% macropores, preferably elongated and in any case interconnected. It is so important for truffle habitats that some species have modified their biological cycle to fruit in sandy soils and in soils with subangular blocky aggregation.

The present report will illustrate the pathways followed by soil-forming processes to achieve the optimal conditions - different for each truffle species - that link the architecture of truffle soils on one side to hydrological and biochemical cycles, on the other to specific soil-landscape units located in fluvial (*T. magnatum*) and dunal landscapes (*T. Borchii*), in slope landscapes with a higher (*T. melanosporum*) or lower content of coarse limestone fragments (*T. aestivum*), and in mountain landforms on limestone and dolomite that favour the accumulation of organic matter in the A horizon and limit the thickness of the overlying organic horizons (*T. mesentericum*).

Despite the advances made by biology and genomics, which have made the cultivation of truffle species increasingly reliable, truffle habitats and productions have continued to decline over the past two decades. It is now clear that reversing the trend can only be achieved through a multidisciplinary approach with strong involvement of soil science. Some of the topics to be addressed would be in-depth studies on the hydrology of truffle soils; the hydraulic uplift with which symbiont plants could hydrate mycorrhizae during drought periods; the relationship between truffle species and soil microbial communities; the preservation of the fertility of truffle grounds through appropriate management of soil organic matter.

<sup>4</sup> Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, CHILE

The significance of the soil microbiome in agriculture is growing due to its role in nutrient cycling, plant growth, and plant disease suppression. Processes like dispersal and environmental filtering influence the soil microbiome, but their real-world impact, especially in underrepresented areas like Chile, the southernmost country, remains unclear. In this study, the influence of natural surrounding areas (shrubland and forests) on orchard soils were explored. Moreover, we hypothesized that the more resemblance in the soil biogeochemical properties the higher similarity of the soil microbiome from orchards to that of forests. We analyzed six basins from Central Chile. In each one, we took 6 soil samples of natural areas (references) and 18 soil samples from orchards at varying distances from natural areas. The analyses of these samples showed that orchards exhibited higher bacterial but lower fungal richness than natural areas. Bray-Curtis analyses revealed significant differences in bacterial and fungal composition, with specific Taxonomical Families displaying distinct patterns. For instance, Solirubrobacteriaceae, Pseudonocaridaceae, and Xanthobacteriaceae were more abundant in forest soils, while Intrasporangiaceae, Roseiflexaceae, and Azospirillaceae dominated orchard soils among bacterial groups. Regarding fungi, Teratosphaericeae, Pannariaceae, and Aspergillaceae were prevalent in forests, whereas Pleosporaceae, Bulleribasidiaceae, and Coniochaetaceae dominated orchards. Functional analysis predicted higher bacterial denitrification in forests and increased chitinolysis and fermentation in orchards. Fungal functional predictions indicated a prevalence of plant pathogenic fungi in orchards and a higher occurrence of endo- and ecto-mycorrhizae in natural soils. The study identified a correlation between the percentage of natural surrounding areas around orchards and microbial diversity, microbiome similarity, and compositional differences. However, there is also an interplay between surrounding areas and the soil biogeochemical properties. In conclusion, this research sheds light on soil microbiome dynamics in real-world environments, providing insights for optimizing microbiome management in agriculture. The findings emphasize the importance of considering both farm-level practices and regional landscape factors for informed decision-making by stakeholders.

#### A SYSTEMATIC LITERATURE REVIEW OF SOIL ECOSYSTEM SERVICES (SES) IN THE SUB-SAHARAN AFRICA

N. NYAMARI<sup>1</sup>, J. MÄSGEN<sup>1</sup>, D. OTIENO<sup>2</sup>, C. BOGNER<sup>1</sup>

<sup>1</sup> University of Cologne, Institute of Geography, Cologne, GERMANY

<sup>2</sup> Jaramogi Oginga Odinga University of Science and Technology, Department of Biological Sciences, Bondo, KENYA

Soil provides foundational services for human well-being. Over-exploitation of soil resources has elicited continuous land and environmental degradation challenges. This has led to a growing interest amongst scholars to understand and produce relevant knowledge to tackle the challenges. Therefore, this review aimed to assess the scope of soil ecosystem services (SES) studies in Sub-Saharan Africa. Using systematic quantitative content analysis (SQCA) in MAXQDA 2020 software, we reviewed 51 studies on soil-related ecosystem services. SQCA was executed by a combination of deductive and inductive content analysis to derive different categories (criteria) from the studies. The categories were; SES types, case studies' geographic scales, modelling tools, analysis perspectives, and drivers of change. From the results, all studies quantified different SES. Only 12, 6, and 3 studies conducted spatial mapping, temporal analysis and stakeholder participation respectively. None of the studies provided a valuation of SES. Forty-two (42) studies analyzed regulating services (81% were on carbon storage), 23 analyzed supporting services, 12 studies assessed food provisioning and 8 studies assessed other SESs. Based on the studies' geographic coverage, 71% focused on local/specific landscapes, 14% on a national scale and 15% on a regional scale. Based on the multi-perspective analysis, 42 studies concentrated on a singular perspective like ecological, economic or social. Only 7 studies analyzed all three perspectives together. There is little application of multi-data integration tools such as Artificial Intelligence for Environmental Sustainability (ARIES), Integrated Valuation of Ecosystem Services and Trade-offs (InVEST) or machine learning algorithms, thus limited multidimensional analysis. Land management practices, climate changes and land use changes were the predominant drivers studied, leaving behind other drivers such as road development. The global focus is to integrate SES into policy analysis and sustainability governance. Therefore, this review contributes to understanding and supporting the existing knowledge base for policy development and implementation.

This paper focuses on pedodiversity within the Shouf Biosphere Reserve, specifically in vineyards, exploring sustainable development opportunities in sectors such as viticulture and ecotourism. The study characterizes and determines the oenological potential of the diverse terroirs across the 300 km<sup>2</sup> region. It suggests conservative viticulture practices to enhance sustainability in vineyards and proposes showcasing soil profiles in wineries to promote ecotourism.

The research contributes to responsible soil management by conducting an inventory of soil categories and subcategories in vineyards and understanding the specific base element of geology as a main contributor to soil pedodiversity. The study also considers climate change and possible adaptation measures.

The research offers agricultural techniques to preserve soil productivity, nutrients, and biodiversity. It identifies various soil types such as Arenosols, Regosols, Leptosols, Cambisols, Luvisols, Anthrosols, Fluvisols, Gleysols, and Calcisols, showing their influence on farmer decisions regarding tillage, variety choices, and planting practices. Furthermore, the study tackles the intrinsic relationship with the substrata and the sourcing of minerals through weathering and dissolution to complement the organic components. It also refers to the contribution of physical and chemical influencing factors of groundwater and surface water. The paper emphasizes the traditional ecological knowledge for a complete approach to sustainable agriculture. It suggests valorizing pedodiversity in ecotourism to enhance sustainability and exploration.

In conclusion, this study not only enhances the understanding of pedodiversity in the Shouf Biosphere Reserve but also proposes practical strategies for responsible soil management. By integrating indigenous knowledge, historical insights, and forward-thinking practices, the research aims at fostering sustainable agriculture, supporting biodiversity, and addressing climate challenges while incorporating pedodiversity into ecotourism initiatives.

#### MAPPING SOIL WATER REPELLENCY IN DENMARK

L. GOMES<sup>1</sup>, P.L. WEBER<sup>1</sup>, C. HERMANSEN<sup>1</sup>, S. GUTIERREZ<sup>1</sup>, A.C.S. DANIELSEN<sup>1</sup>, D. MIKSTAS<sup>1</sup>, C. PESCH<sup>1</sup>, M.H. GREVE<sup>1</sup>, P. MØLDRUP<sup>2</sup>, L.W. DE JONGE<sup>1</sup>

<sup>1</sup> Aarhus University, Viborg, DENMARK

<sup>2</sup> Aalborg University, Aalborg, DENMARK

Soil water repellency (SWR) is a phenomenon that occurs at the microscale and has profound impacts on the hydrological functioning of ecosystems. However, the spatial assessment of SWR occurrence is still underdeveloped at a national scale. Our study used digital soil mapping techniques to map SWR in Denmark at high resolution (10m). We measured SWR in 7,300 soil samples from various locations across Denmark using the molarity of an ethanol droplet test. The SWR observations were associated with spatial covariates related to soil properties (soil organic carbon – SOC, soil texture), vegetation (Sentinel 2), agricultural management (Cropland only/Cropland in rotation), and terrain attributes (slope, saga wetness index). We used a Quantile Random Forest model to train and predict the median SWR values as well as the upper (90<sup>th</sup>) and lower (10<sup>th</sup>) quantiles for the whole of Denmark. Soil organic carbon, soil texture, and vegetation indices were the main factors driving the spatial distribution of SWR. Areas with coarse soil texture and high SOC presented the highest degree of SWR, while the agricultural areas in fine-textured soils were mostly hydrophilic. When analyzing the influence of plant cover, coniferous forests and heath areas presented the highest degree of SWR, whereas deciduous forests exhibited comparably lower values. The combination of soil properties and satellite images allowed us to visualize the difference in SWR between forest species at high resolution. This might be beneficial for predicting and monitoring a wide range of hydrological facets of ecosystems, such as the water erosion risk and plant drought resistance. Overall, these results can help with, e.g., locating areas where SWR can cause problems and areas where SWR may be beneficial for soil water regulation dynamics of the vegetation.

#### EXPLORING THE SYNERGIC EFFECTS OF SALINIZATION AND WARMING ON SOIL ORGANIC CARBON FRACTIONS, AVAILABLE NUTRIENTS, AND SOIL AGGREGATION

M. MDAINI<sup>1</sup>, N. BRAHIM<sup>2</sup>, E. LLORET<sup>1</sup>, M. GONZÁLEZ-ROSADO<sup>1</sup>, A. MORUGÁN-CORONADO<sup>1</sup>, N. SHIMI<sup>2</sup>, R. ZORNOZA<sup>1</sup>

<sup>1</sup> GARSA group, Department of Agricultural Engineering, Universidad Politécnica de Cartagena, Cartagena, SPAIN

<sup>2</sup> Department of Geology, Faculty of Sciences of Tunis, University of Tunis El Manar, Tunis, TUNISIA

Climate change is a global phenomenon, manifesting in various environmental alterations with profound implications for ecosystems. One major outcome is soil salinization in irrigated croplands, with direct impacts on soil functioning. However, understanding the interactions between soil salinization and global warming and their effect on soil functioning proves difficult due to the highly variable environmental conditions. Hence, we conducted a microcosm experiment under controlled conditions, at two different temperatures and three different salinity levels, using soil samples from a semiarid area in northern Tunisia. Our objective was to assess if an increase in temperature can have a synergic effect on soil salinity with negative effects on soil organic carbon, nutrients, and aggregation. We used two factors: soil electrical conductivity (salinity factor; three levels: 1 mS cm<sup>-1</sup>, 5 mS cm<sup>-1</sup> and 10 mS cm<sup>-1</sup>) and air temperature (two levels: 19°C, as current mean annual T of the area, and 21°C, as IPCC projections for 2030-2050). Treatments were randomly distributed in an incubator with five replications per treatment. Soil moisture was gravimetrically kept at 60% of water holding capacity. Soil sampling was performed on days 0 (beginning of the experiment), 10, 20, 40, 60 and 90 for physicochemical analyses and CO<sub>2</sub> and N<sub>2</sub>O emissions. In soil samples we measured soil pH, electrical conductivity (EC), total organic carbon (TOC) and nitrogen, particulate organic carbon (POC), soluble carbon, available nutrients, stable aggregate fractions and aggregate weight diameter. Our results revealed a strong negative relationship between EC and soil pH ( $R = -0.87$ ,  $p < 0.05$ ). These changes in soil salinity and pH were associated to changes in the labile fractions of soil organic carbon and soil aggregation. In conclusion, this research provides valuable insights into the dynamics of soil properties under increasing saline conditions and foreseen global warming. Such knowledge is pivotal for the development of sustainable agricultural practices and effective ecosystem management strategies in salt-affected areas.

<sup>5</sup> Experimental Station of Arid Zones-CSIC, Almeria, SPAIN

The harsh environmental conditions that govern drylands, including water scarcity, high salinity or nutrient poor soils, often result in slow recovery rates after a disturbance. Application of soil microbiome inoculum arises as a promising tool to enhance the success of ecosystem restoration. Specifically native biocrust microbiomes, which are encompassed by many microorganisms including cyanobacteria and bacteria, are considered an interesting biotechnological niche of bioinoculants for soil restoration. Here, we present key results related with the use of native bioinoculants from biocrusts in the restoration of soil functions and seedling growth obtained during more than 8 years by laboratory and field experimentation. Under laboratory conditions, the inoculation of different degraded soils with native biocrust-forming cyanobacteria significantly increased soil organic carbon (SOC) and total nitrogen in up to 10 and 2 g/kg soil respectively, after three months and rapidly promoted soil surface stabilization. Under field conditions cyanobacteria colonization rates were slower, but inoculations also increased SOC in between a 35 and 42% after one year. The application of reducing environmental stress strategies, under field conditions, favoured the establishment and growth of cyanobacteria inoculum, leading to the formation of a biocrust. The combination of biocrust forming cyanobacteria and bacteria not only promoted an increase in the biomass production of heterocistous cyanobacteria but also higher EPS secretion that led to higher soil organic matter content. Moreover, seed biopriming with biocrust-cyanobacteria showed a positive effect on the germination of native annual plants and increased seedling radicle growth, although this effect was species-specific. All these results point the beneficial effect of biocrust inoculants as nature based solutions to facilitate dryland degraded ecosystem restoration. This work is part of TED2021-132332B-C21, project funded by MCIN/AEI/10.13039/501100011033 and UE "NextGenerationEU"/PRTR"

<sup>2</sup> University of Koblenz, Institute for Integrated Natural Sciences, Koblenz, GERMANY

<sup>3</sup> Georg-August-University of Göttingen, Centre for Stable Isotope Research and Analysis, Göttingen, GERMANY

Studying invasive plant species, in this case *Fallopia japonica*, has become pivotal in understanding their biogeochemical implications. Based on previous research that has shown that *F. japonica* inhibits soil nitrification by means of polyphenols, our study employs stable isotope analysis to delve into the biogeochemical niche-building mechanisms of this invasive species. We employed stable isotopes,  $^{13}\text{C-CO}_2$  and  $^{15}\text{N-NO}_3$  and  $^{-}\text{NH}_4$ , to shed light upon the biogeochemical dynamics associated with the invasive prowess of *F. japonica* and find whether it exhibits a higher affinity for ammonium than nitrate when compared to a native species (*Urtica dioica*) and whether it allocates resources predominantly to root growth. If this is indeed the strategy of *F. japonica*, it may indicate a niche-building strategy. It would suggest that *F. japonica* could be carving out ecological niches characterized by specific nitrogen forms and soil conditions, potentially influencing the competitive landscape and ecosystem dynamics in invaded habitats.

Contrary to our hypotheses, our results challenge the belief that *F. japonica* exhibits a higher affinity for ammonium than nitrate compared to native species. Through our labelling experiments on young *F. japonica* and *U. dioica* plants, we discovered that *F. japonica* displays a lower affinity for ammonium than *U. dioica*. Additionally, *F. japonica* showed higher nitrogen-use efficiency and preference for allocating resources to root biomass, underlining its ability to efficiently utilize nitrogen resources. These findings shed light on the intricate mechanisms behind the ability of *F. japonica* to disrupt ecosystems and appears to contribute to its success in shaping and potentially dominating distinct ecological niches within invaded ecosystems. Our work contributes to the ongoing efforts to foster sustainable and efficient agricultural systems in the face of global change.

Recently in the Tuscan Archipelago, young winemakers recovered the historical terracing through the restoration of dry-stone walls and planting new vineyards with various cultivars (e.g., Ansonica). The risks that soil management practices could alter ecosystem services with negative implications on nutrient cycles, pH and water availability thus affecting vine health and productivity.

This study aimed to evaluate the capability of the agricultural practices adopted in terraced vineyards for maintaining natural soil functionality. In October 2022, ten different sites were selected in vineyards and one with Mediterranean shrubs as benchmark (BM).

Soil samples were collected in the vineyard inter-row, at 10 cm depth, for analyzing total organic carbon content (TOC); pH; electrical conductivity; micro- and macro-elements, texture; moisture and microarthropod abundances and Biological Soil Quality index (QBS-ar).

Since the sites are particularly rich in sand (42-70%), with a dominant Sandy Loam texture class (SL), all the soils have scarce available water capacity around 38 mm in the upper 30 cm. In 2022 the climate was extremely dry with precipitations of 350 mm, so even in October soil moisture and TOC averages were very low (<2%). This condition negatively affects the availability of nutrients for soil biota. Over 9,400 microarthropods were collected: the most abundant groups were Acari (74%) and Collembola (17%). The highest QBS-ar value (189) was in BM. The microarthropods' abundance was positively correlated with TOC and negatively with the silty soil component (Pearson similarity index;  $p < 0.05$ ). Conversely, soil moisture did not significantly influence arthropod communities, largely represented by xerophilic or mesophilic species. Moreover, the two-year vineyard sites negatively impacted the arthropod abundance and biodiversity. Vineyard plantation techniques in terraced landscapes need to be more conservative to preserve soil functionality and its ecosystem services. Improving soil functional biodiversity can help vine plants to naturally face climate change and times characterized by drought and high temperatures.

#### RESTORING SOIL ECOSYSTEM SERVICES WITH ENGINEERED SOILS

V. ZUPANC <sup>1</sup>, H. GRČMAN <sup>1</sup>, M. ZUPAN <sup>1</sup>, A. GANTAR <sup>1</sup>, M. PIRNAT <sup>2</sup>

<sup>1</sup> University of Ljubljana, Biotechnical Faculty, Ljubljana, SLOVENIA

<sup>2</sup> Nerinvest, Polzela, SLOVENIA

Soil is a natural resource threatened by human activity. The process of soil restoration is expensive, time-consuming and requires careful planning and cooperation between different stakeholders and sectors. In densely populated regions such as Central Europe, there are two important types of artificial soil ecosystems: the restoration of landfills or mining pits and urban green infrastructure. The need for green spaces in urban areas, e.g. to mitigate the urban heat island effect, requires suitable engineered soils with specific chemical, physical, biological and geotechnical properties.

Engineered soils, made from excavated material and other waste, provide a solution for building the top layer that allows the restored ecosystem to function. These soils provide suitable conditions for plant growth and other ecosystem services. The study gives an overview of the application of engineered soils for the restoration of degraded land. The focus is on the different methods to ensure the proposed hydrological functionality of the soil. The application of engineered soils to target areas is a measure that restores soil functions and enables environmental protection by restoring top layer ecosystem services such as climate regulation, water filtration and storage, and food production.

#### EFFECT OF BIOCRUSTS ON CARBON AND NITROGEN TRANSFER FROM WATER EROSION AND IMPLICATIONS FOR PLANT PERFORMANCE IN DRYLANDS

S. CHAMIZO<sup>1</sup>, J. FERNÁNDEZ-GALERA<sup>2</sup>, E. RODRIGUEZ-CABALLERO<sup>2</sup>, C. URUETA<sup>2</sup>, Y. CANTÓN<sup>2</sup>

<sup>1</sup> Experimental Station of Arid Zones (EEZA-CSIC), Almeria, SPAIN

<sup>2</sup> Agronomy Department, University of Almeria, Almeria, SPAIN

Biocrusts are the living skin of dryland soils and frequently occupy the soil surface among vascular plants. Biocrusts control carbon (C) and nitrogen (N) fixation and nutrient transformations during large periods of the year in which vegetation remains inactive, thus playing a major role in C and N cycling in drylands. Nutrients fixed by biocrusts can be transferred to nearby plants through runoff redistribution processes and provide an extra contribution of resources that can be essential for vegetation in these water- and nutrient-limited environments. However, little is known about C and N transfer from biocrusts through water erosion and how this water and nutrient supply may affect vegetation performance. The objective of this study was twofold: i) examine biocrust effect on C and N transfer via water erosion; and ii) evaluate the effect of biocrust run-on (water and associated nutrients) on plant performance. Runoff was monitored after different rainfall events in bare- and biocrust-covered plots in a semiarid ecosystem from SE Spain (Tabernas desert), and total organic C and N exported in water and sediments were quantified. In addition, the effect of biocrust run-on on plant performance was evaluated by comparing plants (*Machrochloa tenacissima*) receiving and excluding this water and nutrient input. Our results show that dissolved organic C and N were higher in runoff from biocrust-covered plots, however total organic C and N losses were higher in bare plots due to the greater erosion rates recorded in these soils. Runon contribution from biocrusts had an important role in plant productivity. Plants which received water and nutrients from biocrust runon had greater photosynthetically active biomass and net C uptake rates than plants under runon exclusion. Our results highlight the importance of the resources provided by biocrusts (water, C and N) through water redistribution processes in the performance of vegetation from drylands.

#### THE NEED FOR SUSTAINABLE SOIL RESOURCES MANAGEMENT

M. ZLATIC

Belgrade University, Faculty of Forestry, Belgrade, SERBIA

According to its natural characteristics, Serbia is predisposed to erosion processes. However, both worldwide and in Serbia, a large percentage of erosion processes are contributed by anthropogenic factors. The activity of man can be both negative and positive, depending on the degree of awareness of the importance of using natural resources on the principles of sustainability.

Preventing the degradation of torrential floods and erosion processes contained in the sustainable management of land resources, which includes the use of participatory methods. The paper presents the participation of the community in the management of natural resources (CBNRM – Community-Based Natural Resources Management), according to which the community becomes the primary implementer, with the assistance and under the supervision of professional services. The case of public participation in the sustainable management of land resources of Grdelica Gorge (South Serbia), shows the socio-economic and ecological approach of the local population.

This paper also presents a model of sustainable management of land resources, adapted to the conditions of hilly areas of Serbia, which includes the planning of production on sloping terrain from the aspect of land resources, then the needs of the population for certain localities particular production, and profitability of planned production. Regarding the ecological effects of the model of SLM, soil loss is reduced under the level of tolerance in the researched area. The economic effects of the established model of SLM, proved by Benefit-Cost Analysis, are on satisfactory to a significant level. These reasons are enabling people to stay and survive in these regions.

#### LINKING SOIL ORGANIC CARBON CONTENT TO SOIL COMPONENTS IDENTIFIED USING NONNEGATIVE MULTIVARIATE CURVE RESOLUTION OF MID-IR SPECTRA: A PHYSICOCHEMICAL MODEL

M. BORISOVER <sup>1</sup>, M. LADO <sup>2</sup>, G.J. LEVY <sup>3</sup>

<sup>3</sup> Institute of Soil, Water and Environmental Sciences, ARO, RISHON LEZION, ISRAEL

Soil organic matter (SOM) is recognized to control soil properties and functioning. Accounting for SOM content and its compositional characteristics is essential for developing soil health indices. Mid-infrared (IR) spectroscopy is commonly used for relating soil IR spectral fingerprints to soil organic carbon (SOC) content, employing different mathematical techniques, in particular, such as partial least square regressions. Generally, developed mathematical models that link soil IR spectra and SOC content are empirical, and their interpretation is not necessarily simple. In this presentation, a new approach is proposed, whereby a physicochemical multi-component model, extracted from mid-IR spectra using nonnegative multivariate curve resolution (MCR), is linked to SOC content. This model explores (i) the potential of the nonnegative MCR to decompose IR spectra into contributions of chemically meaningful soil components each associated with a specific organic carbon (OC) content, and (ii) the Bouguer-Beer-Lambert law. Soil samples (216) were collected from different regions of Israel under different land uses and from two depths (0-10 and 30-60 cm). Mid-IR absorption spectra of each soil sample determined in KBr pellets were decomposed into the contributions from four components. Each component of the four identified represents an organo-mineral complex, such that the four components allowed reasonable representation of SOC content for SOC < 1% w w<sup>-1</sup>. Above this threshold, a distinct failure of the model in representing SOC content was detected. The failure was interpreted as an indication that SOM becomes either enriched by a particulate fraction or the links between SOM molecules and mineral surfaces become more elusive, such that mineral fingerprints in IR spectra are less effective in indirectly representing SOM contribution. The underlying assumptions of the model and further perspectives of its use are discussed. An observed severe failure in the ability to predict SOC content above a certain SOC threshold can be very useful for detecting different fractions of organic matter in soil, with potentially different stability and contribution to SOC storage capacity.

Interest in soil microhabitats has increased considerably leading to a better understanding of the interaction of soil microorganisms with their local environment. While the rhizosphere and detritusphere have already been very well studied, a microhabitat that remains largely unexplored is the mineralosphere. This microhabitat is the specific interface comprising mineral surfaces and the surrounding soil, which is physically, chemically and biologically influenced by minerals. In the frame of the Biodiversity Exploratories project (<https://www.biodiversity-exploratories.de/en/>) we performed a series of mineral exposure experiments to study the microbial colonization of goethite and illite in grassland and forest ecosystems under different land-use intensity for up to five years. In grasslands, fungi colonized minerals faster than bacteria and incorporated <sup>13</sup>C labelled substrates into their biomass to a greater extent than bacteria. In forest soils, the fungal colonization of the mineral habitat was driven by taxa-specific preferences for the C- and nutrient-poor microhabitats. Fungal trophic guilds responded differently to the different types of secondary minerals with the ectomycorrhizal community being less affected by differences in organic matter (OM) sorption capacity between goethite and illite than the saprotrophic fungal community. Fungi likely contributed to the formation of mineral-associated organic matter. Land use influenced the input of OM and nutrients into the mineralosphere, and thus, the biomass, community structure, and functionality of mineral-associated microorganisms.

#### METHODS OF SOIL ORGANIC MATTER ANALYSIS IN FOREST SOILS

M. VERRILLO, G. ROSSI, S. CANGEMI, F. SCOGNAMIGLIO, R. SPACCINI

UNIVERSITY OF NAPLES FEDERICO II, NAPLES, ITALIA

The forest soils represent a useful reference system to test the analytical protocols aimed at analyzing the soil organic matter (SOM) characteristic and dynamic, based on the larger organic carbon (OC) content and the variable composition of organic inputs. The present study combines two different extraction methodologies with the detailed characterization of SOM fractions applied on two forest systems represented by *Quercus ilex* L. and *Fagus sylvatica* L.

The first approach is based on the conventional alkaline extraction of humic substances followed by the characterization of OM fractions performed by solid state  $^{13}\text{C}$  NMR and off-line pyrolysis GC-MS. A complementary extraction procedure relies on the sequential fractionation of SOM with the preliminary selective removal of various lipid fraction identified as an essential pool for the progressive stabilization of SOC and a useful tool to identify the main origin of SOM components. The main differences were related to a larger content of free lipid molecules of ilex-forest soil, while the beechwood samples revealed a larger amount of lignin derivatives and recalcitrant hydrophobic alkyl compounds. The  $^{13}\text{C}$ -CPMAS-NMR spectroscopy of humic fractions indicated a selective incorporation of aromatic and alkyl compounds in soil under *Fagus sylvatica*, while the alkaline extracts from soil of ilex systems showed a prevalence of polysaccharides and peptidic derivatives. The results of sequential fractionation showed that 33% of extractable OC from the system under *Quercus ilex* is concentrated in the free or unbound lipid fraction, while in the beechwood soil about 32% of total OC is represented chemically bound long chain aliphatic molecules from biopolyesters originated from root tissues. The predominance of recalcitrant aromatic and aliphatic organic molecules in *Fagus* system may be associated to the observed slower SOC turnover. The application of two complementary methodologies improves the evaluation of SOM composition and may provide a useful support to understand the SOC dynamic in agro and forest ecosystems.

#### LAND RESOURCES DEGRADATION IN BANGLADESH: AN EMERGENCE ON CARBON-SMART FARMING

M.J. UDDIN

Department of Soil, Water and Environment. University of Dhaka, Dhaka, BANGLADESH

Soil organic carbon (SOC) is an essential component for soil health and quality maintenance. To counteract nutrient mining, soil health should be prioritized to provide food security and ecosystem restoration. However, the level of SOC has been falling rapidly in Bangladesh's high and medium high land areas as a result of intensive farming methods and poor management. In Bangladesh, high and medium high land account for approximately 50% of agricultural areas utilized for intensive crop production, housing, settlements, brick fields, fishponds, settlements, and other facilities. As a result, higher lands are disappearing at an alarming rate, whereas SOC are also declining due to low residual input and greater cropping intensities with no fallow periods. Furthermore, most agricultural soil becomes excessively acidic due to overuse of chemical fertilizers and pesticides. Consequently, the physical fertility of the soil is deteriorating the agricultural production scenarios. Given these concerns, a study was carried out to compare the impacts of peanut residues on soil quality and bio-resource management to other green residues. It was found that over the course of a year, SOC and pH levels in peanut-treated soils increased to the required level. Thus, peanut residues are a valuable and necessary solution for enhancing soil quality in agricultural fields in Bangladesh or similar climatic zones. Therefore, sustainable soil management strategies, such as C-smart farming, should be considered as an essential option through conservation agriculture, the use of organic amendments, climate resilient cropping patterns, and soil intelligent approaches.

<sup>5</sup> Leibniz University of Hannover, Hannover, GERMANY

Among the current global challenges, the research of new practices aimed at mitigating soil impoverishment, exacerbated by the pressing climate changes, is the most urgent. Studying soil organic matter (SOM) dynamics and comparing the conventional intensive farming practices with the emerging alternative sustainable ones can represent a key indicator in soil health investigation, helping to find new guidelines for conservative agroecosystem management. In this study, the soil from a Mediterranean olive orchard, with both sustainable (Smng) and conventional (Cmng) land use for 21 years, was investigated for its physicochemical properties, with particular attention to OM from aggregates and its interaction and distribution in aggregates and depths. A higher amount of total carbon (+50.7%) and nitrogen (+74.9%), as well as of OM aromatic component (+76.0%), was detected in the first analyzed layer (0-5 cm) in the sustainably managed soils compared to the conventional one, a sign that the organic matter from surface deeply penetrates very slowly. This evidence was highlighted especially in micro-aggregates (<0.063 mm) (C = +59.3%; N = +86.7%; OM aromatic component = 87.7% in the Smng), likely due to their capacity to bond more easily the smaller colloidal particles with a higher specific surface. This trend is also reflected in an increase in bacterial abundance and in a different accumulation of organic compounds deriving from microbial fermentation processes in Smng soils, as highlighted by the OM qualitative characterization. The soil mineralogical analysis showed that minerals maintained a higher crystallinity in Smng than in Cmng, where soil tillage promoted their alteration. Moreover, Fourier-transform infrared (FTIR) spectroscopy analysis highlighted that soil disturbance due to the Cmng can affect SOM stability, also creating different spatial distributions in the particle aggregates and soil depths. Distinguishing SOM quality, stability and interaction with mineral components can help to understand its degradability and dynamics, both essential for mitigating the effects of climate change and promoting land protection.

CONTRASTING SEQUESTRATION CHARACTERISTICS OF SOIL ORGANIC CARBON IN PADDY AND UPLAND SOIL FROM SOUTHERN CHINA TYPICAL RICE TERRACES

Z. ZHAO, G.X. PAN

Nanjing Agricultural University, NANJING, CHINA

Soil organic carbon (SOC) sequestration capacity and the underlying mechanism under long-term sustainability agro-management is the frontier of basic research of sustainable agriculture. Rice terraces in the mountainous areas of southern China have been recognized as globally significant agricultural heritages. Investigating their SOC accumulation under rice cultivation over a millennium scale would be advisable for establishing nature-based solutions for SOC sequestration in rice agriculture. This study selected nine representative rice terrace systems from mountainous areas in southern China. Undisturbed topsoils (0-20 cm) from three paired adjacent paddy and upland fields were collected respectively from these nine terrace paddies. By quantifying the plant (lignin phenol)- and microbial (amino sugar)- derived C in soils, we identified that SOC accrual was achieved via contrasting pathways in paddy and upland soils. Paddies were 27.9% more efficient in SOC sequestration than their adjacent upland counterparts, with greater differences in clayey soil than sandy soils. Upland soils were more enriched by microbial-derived C, whereas paddy soils were replenished with a greater proportion of plant-derived C. Moreover, the composition, community structure, and activity of microorganisms differed between paddy and upland soils, due to the anaerobic conditions induced by the waterflooding in paddy soil, which affected the decomposition and sequestration efficiency of organic carbon by microorganisms in the two soils. Hence, as anthropogenic wetlands, rice terrace systems play a vital role in preserving global soil carbon stocks and alleviating climate change by conserving and enhancing their carbon storage.

#### SOIL ORGANIC CARBON DYNAMICS AND P LEGACY IN LONG-TERM MANAGED AGRO-ECOSYSTEMS ACROSS EUROPE

P. BHOPLÉ, D. WALL, K. RICHARDS, F. BRENNAN, G. LANIGAN, G. BONDI

Teagasc, Crops Environment and Land Use Department, Johnstown Castle, Wexford, IRELAND

The assessments of soil organic carbon (SOC) in agro-ecosystems is crucial to evaluate carbon (C) sequestration potential in agricultural soils and guide management strategies. The interaction among soil C, nitrogen (N), and phosphorus (P) plays pivotal role in soil organic matter (SOM) dynamics, but also the nutrient availability in agro-ecosystems influence SOM cycling and C storage. Despite this, the impact of P fertilizer addition on C and N cycling remains largely unexplored.

Hence, to determine the influence P fertilization has on SOC stabilizations in agricultural systems, ICONICA project is investigating a unique set of long-term P fertilizer experiments (LTEs) across Europe, including a range of P treatments to establish relationships between P legacy and C sequestration. In this study, soils up to 50 cm depth were collected from six LTEs distributed across Europe including different soil types, land uses and agricultural management regimes. The objective of the work was to provide initial reference value of soil C stored at depth across P treatments. Furthermore, this study investigated C pools partitions within soil particles across managed sites to assess the C stored in mineral-associated soil fractions (MAOM). The average SOC stocks in arable (AR) sites ranged between  $21.22 \pm 1.19$  to  $18.60 \pm 2.35$  (tC/ha). Higher SOC stocks occurred in the grassland (GR) sites ranging from  $54.76 \pm 6.65$  to  $43.07 \pm 5.71$  (tC/ha). The majority of SOC was associated to the subsoils (10-30 cm) in AR and to the top soils (0-10 cm) in GR. For both AR and GR sites, the MAOM fraction accounted for higher associated SOC compared to particulate organic matter (POM) within coarse (cPOM) and fine (fPOM) fractions, perhaps with indicative differences among land uses. Overall P legacy has a variable effect on C storage across different land uses. Preliminary results will be presented to elaborate the role of P management in different agro-ecosystems and to understand its effects on C cycling, highlighting the optimal soil and P management scenario for SOC storage.

#### EFFECTS OF LONG-TERM SOIL ORGANIC MATTER DECLINE ON SOIL NUTRIENT STATUS AND ORGANIC MATTER COMPOSITION IN ORGANICALLY MANAGED GRASS-CLOVER LEY AND PERMANENT PASTURE IN NORWAY

J ZETHOF <sup>1</sup>, T F RITTL <sup>2</sup>, M EBBESVIK <sup>2</sup>, R POMMERESCHE <sup>2</sup>, J M ZENNER <sup>1</sup>, K SCHÜTZENMEISTER <sup>1</sup>, H.F. JUNGKUNST <sup>1</sup>

<sup>1</sup> Institute of Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Landau, GERMANY

<sup>2</sup> Norwegian Centre for Organic Agriculture (NORSØK), Tingvoll, NORWAY

Grasslands are often seen as a beneficial measure to increase soil organic matter (SOM) content in croplands and reduce GHG emissions. In permanent grassland continuous ground cover and high root density protect the soil against erosion, leading to an accumulation of SOM. In cultivated grasslands, such as grass-clover leys, the nutrient cycle encompasses an accumulation phase during the ley period, followed by a rapid decomposition after ley termination. Upon ploughing the grass-clover ley, there is an increased mineralization of nutrients, contributing to soil fertility buildup. As part of the global C-arouNd project, which aims to investigate how short and long-term agricultural management practices affect SOM persistence, we want to investigate how long-term SOM decline affect the soil nutrient status and organic matter composition in a permanent and cultivated grassland in West Norway.

At Tingvoll experimental farm, organic milk production was established in 1986, replacing the previous conventional sheep farming. Since 1990, soil samples (0-20cm) have been taken every 5–7-year for determination of SOM and soil fertility status. Grass-clover yields have been annually measured since 1991. Preliminary analyses show a decline of SOM (ignition loss) in the 0-20cm toplayer. On average in the cultivated grassland, SOM concentration declined from 14.0% and 7.9% in 1990 to 7.4% and 6.4% in 2021. In the permanent pasture the losses of SOM content were smaller: on average SOM decreased from 10.2% to 8.0%.

We hypothesize that fields with the largest decline in SOM over the past decades will contain relative more stable carbon components while also being richer for most macronutrients. Nutrient imbalances can lead to stronger SOM turnover, meaning that there have not been reached a steady state yet and a further decrease in SOM content can be expected. To test these hypotheses, soil samples will be taken in 2024 to study macronutrients and SOM composition in more detail. SOM composition will be examined using a thermal fractionation method on the different size fractions of the soil.

The depletion of soil organic matter (OM) is a pressing issue affecting many cultivated areas due to changes in land use and intensive farming methods. These changes lead to carbon level reduction, driving soil degradation, decline in soil quality, and erosion. They also influence soil greenhouse gas emissions/absorption, depending on soil management, thus affecting global warming. Hence, it is imperative to mitigate carbon losses.

Using biowastes as OM amendments is a promising approach for restoring degraded soils that aligns with the bioeconomy concept of transforming waste material into valuable resources. However, typical OM amendments undergo short or medium-time degradation, even when organic C is stabilised (compost). Consequently, they often fail to increase soil C stock stably. Hence, more stabilised and protected forms of organic-C are required.

In natural soils, OM stabilisation and protection from decomposition occur by two mechanisms based on the combination of an organic phase with an inorganic component: i) physical exclusion upon aggregate formation of organic and inorganic particles held together mainly by biopolymers, thus hampering the access of microorganisms to OM and ii) chemical bonding of OM with soil minerals causing mineral-associated organic matter (MAOM) formation.

In this study, we aimed to recreate stable organo-mineral aggregates by mimicking both the strategies above and the particulate and fibrous characteristics of the natural organo-mineral aggregates. In detail, organo-mineral complexes based on hydroxyapatite-lignin (HPL) nanoparticles obtained by the wet-chemistry route were then encapsulated into polymer nanofibrous networks through electrospinning nanotechnology. Besides, such nanostructured hybrid composites recruited lignin obtained from agro-industrial biowastes. Nanofibrous architectures of tunable size from the nanoscale to the macroscale were finally generated to form aggregates for OM amendments.

The novelty of this study resides in employing a technologically advanced approach that, hiring agro-industrial biowaste, recreates artificially soil-like micro- to macro-aggregates characterised by prolonged stability of the organic moiety used, thus reliably increasing soil C stock, mitigating carbon losses, improving soil quality in sustainable agriculture.

#### REVEALING THE STABILITY OF ENHANCED SOIL CARBON POOLS BY PERENNIAL GRASS AND LEGUMES AND THE CONTRIBUTION OF MICROBIAL NECROMASS

Y. SHANG, Z. LIANG, P.E. LÆRKE, J.E. OLESEN

Department of Agroecology, Aarhus University, Tjele, DENMARK

Perennialization and integrating legumes in cropping systems are believed to be effective strategies for agricultural soil carbon (C) sequestration. In alignment with this, based on a 10-year experiment in Denmark we previously found increased topsoil C stocks in perennial grass festulolium (PG) and grass-legume mixture (GL) compared to maize monoculture (MM). However, the stability of the increased C and the underlying mechanisms remain unrevealed. Particulate organic matter (POM) mainly includes partially decomposed plant litter and exudates and is usually considered a labile C pool, while mineral-associated organic matter (MAOM) consists of a large proportion of microbial residues (e.g., necromass) that can persist for decades to centuries with multiple protection mechanisms. To further identify the dynamic of different C pools (i.e., POM and MAOM) and reveal the contribution of microbial necromass carbon (MNC), we examined the distribution of C between POM and MAOM and quantified the MNC in POM and MAOM in the three cropping systems (PG, GL, and MM) across 1 m soil depth. We hypothesize that: 1) PG and GL increase POM-C over MM in topsoil (because of less soil disturbance) and subsoil (because of high plant organic inputs); 2) MNC contributes to half of the MAOM-C but occupies little proportion in POM-C; 3) GL increases MNC over PG across 1 m depth (because of the inputs with lower C:N ratio). Our study aims to enhance the current understanding of the role of microbial necromass in soil C sequestration and provide new insights into agricultural soil C sequestration by regulating plant C input and microbial turnover.

<sup>3</sup> ELTE Eötvös Loránd University, Dept. of Environmental and Landscape Geography, Budapest, HUNGARY

The continuous accumulation of organic micro-pollutants (OMPs) in the agricultural environment can increase environmental impacts. Their behaviour in soils is mainly affected by soil organic matter (SOM). Since these compounds have an influence on soil microbiota, these also have a feedback effect on SOM.

Therefore, our research aims to reconstruct the competitive adsorption and desorption processes of three PhACs and their metabolite (Carbamazepine (CBZ), Trans-carbamazepine (TCBZ), 17L-ethynylestradiol (EE2), 17B-estradiol (BE2), 17L-estradiol (LE2), Estrone (E1), Estriol (E3), Diclofenac-sodium (DFC), 5-Hydroxydiclofenac (5-HDFC)), considering the transformation of SOM. We supposed that PhACs as substrates would increase microbial enzyme activity, whereas the DKL and CPX would decrease it as incubation progresses.

A series of 90-day incubation experiments were performed, in which soils were pretreated with defined concentrations of OMPs (listed pharmaceuticals, fungicide (difenoconazole (DCL)) and antibiotic (ciprofloxacin (CPX)). The adsorption and desorption processes were modelled on pretreated samples at different time points using continuous fixed-bed column experiments. Microbial activity and soil parameters were also monitored.

Experimental results show that enzyme activity increases in the initial incubation phase in soil samples treated with PhACs, PhACs+DKL and PhACs+CPX. However, enzyme activity decreases in all treatments at the end of incubation. The sorption results also show similar dynamics, with a decrease in the adsorbed amount at the end of the incubation period (e.g. EE2 at 14. days 0.858 µg/g to EE2 at day 48 days 0.370 µg/g). By reducing the activity of some microbial and fungal strains, the activity of other strains increased during the initial incubation phase, which promoted the transformation of OM and thus reduced potential sorption sites. OMPs in the environment can, therefore, increase microbial activity, which can accelerate the transformation of OM in the soil.

The study was funded by Hungarian Scientific Found (project no. K142865) and ELKH (Project no SA41/2021).

Although soil organic carbon (SOC) is a key element for soil health and climate change mitigation, our understanding of its dynamics is still incomplete. In general, it is thought that the vast majority of SOC in deep soils comes from roots and plant litter and that it is very stable because it is preserved in the mineral phase. The present study aimed to investigate the common paradigm of high stability of SOC in deep soil horizons in semiarid Mediterranean cultivated environments. Here we show that, contrary to expectations, SOC biodegradability increased with depth, indicating that subsoil SOC is potentially less stable than topsoil SOC. We further observed that SOC biodegradability was strongly positively correlated with its radiocarbon age, implying that SOC stability decreases with increasing mean residence time. We explained these original counterintuitive results by a significant contribution of geogenic organic carbon, which proved to be both very old and highly biodegradable, in a context of very low inputs of organic carbon via net primary productivity and amendment restitution. This study highlights the great vulnerability of the millennia-old organic carbon pool stored in deep Mediterranean soils and, more broadly, the key role of geogenic organic carbon in carbon cycle studies.

Soil lipids are an important fraction of organic matter (OM) and play a crucial role in soil organic carbon (SOC) sequestration. However, the origin, fate, and molecular properties of soil lipids are not yet well understood. Such insights are crucial to constrain SOC cycling under changing climate and/or land-use conditions, as well as the information gathered from lipids as biomarkers. For this, we performed a global synthesis of lipid distribution regulated by environmental factors using published nuclear magnetic resonance (NMR) data, as well as case studies to investigate stabilization mechanisms of soil lipids at the molecular level using a combination of density fractionation and pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS).

Based on the collected data, coniferous forests had a greater portion of soil lipids than grassland or cropland. The lipid distribution patterns among different land-use types seemed to be regulated by soil pH values. In a case study of coniferous soils (lipid-rich), compounds with hydroxyl groups were more likely distributed in aggregate-occluded OM and mineral-associated OM than in free particulate OM, whereas weighted abundances of the hydroxyl group in aggregate-occluded and mineral-associated OM were negatively correlated to SOC mineralization rates. This suggests that the hydroxyl group is likely to promote lipid stabilization in aggregates and associated with mineral surfaces. This finding was further supported by a smaller contribution of hydroxyl lipids in a case study of grassland/cropland soils (lipid-poor). The results suggest that the presence of hydroxyl groups promotes lipid stabilization in coniferous forests, and may explain the lipid accumulation among different land-use types at the global scale. We also propose that plant-derived lipids rich in hydroxyl groups can be directly stabilized by interacting with soil aggregates and minerals, in addition to the current paradigm that microbial necromass is preferentially stabilized with mineral surfaces.

#### RECOVERY RATE AND SURFACE PROPERTIES ASSESSMENT OF UV-AGED AND PRISTINE MICROPLASTIC FROM SILT LOAM AND SANDY SOILS IN GERMANY

L. SHAFEA, A.Y. RODRIGUEZ CARLOS, M.O. GOEBEL, S.K. WOCHER, V.J.M.N.L. FELDE, L. SAUHEITL, S. PETH

Institute of Soil Science, Leibniz University Hannover, Hannover, GERMANY

Numerous approaches exist to sample, extract and detect microplastics (MP; 0.001- 5 mm) from the soil environment. However, knowledge about the recovery rates of aged particles, as the most abundant plastic particle type in soil, is still very limited. Besides, pristine and UV-aged MP are likely to behave differently in the environment due to their different surface properties. Therefore, we aimed to set up a systematic laboratory protocol to detect and compare the recovery rate of UV-aged and pristine MP and assess the associated changes in physicochemical properties of the MP particles related to ageing and sample treatment. For this purpose, an experiment was conducted by adding pristine and UV-aged MP particles (exposure time 35 d) of polyethylene terephthalate (PET) and polystyrene (PS) at three sizes (S: <500 µm, M: 500-630 µm, L: 630 µm-1000 µm) to a sand and a silt loam soil at a concentration of 0.5 % w/w. The MP particles were extracted from soil samples by filtration using high-density solutions, followed by an H<sub>2</sub>O<sub>2</sub> treatment to remove organic matter from the samples. The recovered MP was quantified gravimetrically. The recovery rates of pristine and UV-aged particles were the same for both PS and PET, with no significant differences between the different soil types. The changes in physicochemical properties after UV-treatment and after subsequent recovery were analyzed by Fourier-transform infrared (FTIR) spectroscopy, Nile red staining, and contact angle measurements to examine to which degree ageing and extraction altered the polymer properties. An increase in contact angle of MP particles after recovery in UV-aged samples was observed, highlighting the need to consider the ageing effects when assessing their environmental interactions (e.g., mobility). The impact of H<sub>2</sub>O<sub>2</sub> treatment varied between UV-aged and pristine ones, in which the surface properties of recovered UV-aged samples were re-altered. In conclusion, the examined recovery method proved effective for both pristine and UV-aged MP across all size fractions and textures.

#### DETECTING EARLY LDPE BIODEGRADATION BY USING FT-IR AND RAMAN SPECTROSCOPIES

V. ZUFFI <sup>1</sup>, F. PULIGA <sup>1</sup>, D. BALDO <sup>1</sup>, D. CAVATORTA <sup>1</sup>, A. ZAMBONELLI <sup>1</sup>, O. FRANCIOSO <sup>1</sup>, S. SANCHEZ CORTES <sup>2</sup>

<sup>2</sup> Instituto de Estructura de La Materia, IEMCSIC, Madrid, SPAIN

Low-density polyethylene (LDPE) mulch films are widely used in agriculture, accounting for over 40% of all plastics used. However, their large-scale use and improper disposal have resulted in a high residue quantity in the soil, ranging from 72-259 kg/ha. The plastic residues degrade at an extremely slow rate, leading to their accumulation in all environmental compartments. This study aimed to evaluate the ability of the fungal species isolated from plastic debris collected in two distinct agricultural fields to grow and decompose LDPE in a laboratory setting. The degradation of LDPE was evaluated using micro ATR-FTIR, Raman, and SERS spectroscopies, as well as SEM.

Our results showed that out of the 47 fungal isolates obtained, only 11 were able to grow and colonize the LDPE film. After a 90-day trial, only one isolate of *Cladosporium cladosporioides* (Clc/1) was able to initiate the degradation of the LDPE film. The FTIR and Raman spectra showed a significant decrease in the relative intensity of the methylene group bands after *Cladosporium cladosporioides* Clc/1 growth. Similarly, the SERS spectra of LDPE confirmed the decrease in methylene group bands and the emergence of other bands associated with the LDPE polyphenolic mixtures. Finally, SEM analyses revealed the presence of small cavities and circular-shaped depressed areas in the tested LDPE samples, confirming the early degradation process of this material. In conclusion, the early stages of LDPE degradation can be explored using ATR-FTIR, Raman, and SERS spectroscopies in combination with SEM techniques, without the need for any sample pretreatment.

**RETENTION AND ABRASION OF MICROPLASTIC FIBERS IN POROUS MEDIA**

N. COHEN, A. RADIAN, Y. EDERY

Technion university, Haifa, ISRAEL

The reuse of sludge in agriculture practices introduces high amounts of microplastic (MP) fibers originating from synthetic textiles; however, little information is available on their fate in soils. In this study, we established a novel protocol enabling precise slicing of common textile fibers, polyester and nylon, to relevant environmental sizes and characterized their transport in sand columns. The fibers were highly retained even under unfavorable retardation. Smaller fibers were slightly more mobile, and nylon showed marginally higher mobility than polyester fibers. Some fibers peeled and split as they flowed through the soil pores, forming thinner, shorter and more mobile fibers.

We then delved deeper to characterize the transport and retention behavior of polypropylene fibers from an N95 mask using a porous microfluidic cell under a microscope. We discovered that not only fiber length but also its curvature influences its ability to move and tumble through a porous medium. Additionally, retained fibers at pore throats caused significant changes in the flow paths.

Overall, our results suggest that in agricultural settings, the mobility of microplastic fibers is negligible and will lead to their continuous accumulation in the soil. However, MP impacts on the soil environment may change with time due to MP fragmentation, which will increase their mobility and may lead to ground water pollution.

<sup>3</sup> Institute of Soil Science and Land Evaluation, Soil Biology Department, University of Hohenheim, Stuttgart, GERMANY

Plastic mulching films are widely used in agriculture for enhancing crop productivity and weed control. However, their impact, due to non-biodegradable materials like polyethylene, is of growing environmental risk. Indeed, these films can persist in the soil for several years after use, contributing to plastic pollution and contrasting sustainable agricultural. Therefore, the development of biodegradable, eco-friendly alternatives is critical. The PRIN Mulching+ project aiming to make innovative bio-based mulching films using carboxymethyl-cellulose, chitosan, and sodium alginate, and enriched it with N and P salts acting as slow-release fertilizer. The purpose of this study was to evaluate the degradation of these innovative films after burial in the soil, i.e. their impact on the dynamics of available N and P, and on the microbial biomass, community and activity, in order to evaluate their suitability as alternatives to conventional plastic films. Four film types, varying in chitosan-cellulose ratios and  $\text{NH}_4\text{H}_2\text{PO}_4$  addition, were tested. The experiment involved burying 0.1%(wt%) of the film in pre-wetted soil, to simulate the field conditions. Soil samples were collected 30, 60, 90 and 120 days after burial to estimate soil MBC and MBN, inorganic N and available P, as well as the composition and abundance of the main microbial groups and 5 enzymatic activities. The ammonium, nitrate and phosphate levels were influenced by the presence of  $\text{NH}_4\text{H}_2\text{PO}_4$ . A notable increase in MBC and MBN was observed 30 days post burial. Lipase activity, indicative of polymers degradation, increased with films presence. Carbon cycle-related enzyme activities rose proportionally to MBC increases, and increased levels of N-acetyl- $\beta$ -glucosaminidase in soil were observed in correlation with the use of films containing higher amounts of chitosan. Notably, films addition, especially those  $\text{NH}_4\text{H}_2\text{PO}_4$ -enriched ones, led to increased fungal relative abundance and reduced gram-positive bacteria by the incubation end.

These results are promising for the use of these innovative films in agriculture. Ongoing work aims to trace soil C fate and identify the degrading microbial groups using  $^{13}\text{C}$ -labeled films.

#### SOURCES AND FATE OF BIODEGRADABLE PLASTICS IN AGRICULTURAL SOILS

C. COUTRIS <sup>1</sup>, P.A. RIVIER <sup>1</sup>, E.J. JONER <sup>1</sup>, A.B. AAS <sup>2</sup>, L. SOLLI <sup>1</sup>

<sup>2</sup> Norwegian Institute of Bioeconomy Research (NIBIO), Department of Biogeochemistry and Soil Quality, ÅS, NORWAY

Since the 1950s, the use of plastics in agriculture has helped solving many challenges related to food production, while its persistence and mismanagement has led to the plastic pollution we face today. Soils are no exception and concentrations of polyethylene mulch debris up to 380 kg/ha have been reported in Chinese agricultural soils. Biodegradable plastic products have thus been developed to solve plastic pollution through complete degradation after use. But the environmental conditions for rapid and complete degradation are not always fulfilled, and the risk that biodegradable plastics could also contribute to plastic pollution must be evaluated.

Here, we want to share the knowledge gained through research projects on biodegradable plastics, where we studied the degradation of biodegradable mulch under Nordic soil conditions, and the fate of biodegradable plastics in two major soil amendments: compost and biogas digestate.

A two-year field experiment with biodegradable mulch buried in soil in mesh bags showed that also under colder climatic conditions does degradation occur, involving fragmentation already after 2 months, but that complete degradation may take 3 to 9 years, depending on soil temperature and soil organic matter content (both correlate positively with degradation rate). Accumulation is therefore likely to happen when biodegradable mulch is repeatedly used every year.

A full-scale experiment with compostable plastic cups at an industrial composting plant, where we followed their fate and conducted metagenomic analysis over 13 weeks, demonstrated the major role played by fungi during degradation. However, the successful management of biodegradable plastic products largely depends on existing waste management infrastructure. Most biodegradable plastic bags, labelled as compostable and used for food waste collection do not end up in industrial composting plants in Norway, but in biogas production plants. Here, we showed that these plastic bags are only marginally degraded during biogas production, and likely to end up in biogas digestate and then in soils, unless digestate is treated to remove plastic residues.

Microplastic contamination, an emerging problem affecting both aquatic and terrestrial ecosystems, is due to the difficult degradation of plastic materials and their progressive fragmentation driven by various environmental agents. Since the impact of microplastics on soil is still unclear, this work aimed at evaluating the impact of different quantities [0 (CTR), 1, 2 % v/v] of 1-0.25 mm HDPE particles on physical, chemical, and biochemical properties of the A horizon of a soil developed from fluvio-lacustrine sediments and classified as Typic Ustorthent (Soil Survey Staff, 2014). A field experiment was arranged in the experimental station of the DSA3-University of Perugia (Italy), according to a randomized complete block layout with four replicates for each treatment. The monitoring lasted about 2 years, during which the CTR and treated plots were sampled periodically and CO<sub>2</sub> fluxes from the soil to the atmosphere were measured. The CO<sub>2</sub> soil emissions in the treated soils with 2% microplastics were generally lower than the soils treated with 1% and CTR from about 3 months after the addition of microplastics to the end of the trial. This trend could be attributed in the short term to a decrease in microbial abundance, expressed as the sum of all EI-FAME biomarkers, and in a longer period (6 months after HDPE addition) to an improved energy resource use efficiency by the microbial community of the soil treated with the highest dose of microplastics, as suggested by CO<sub>2</sub>-C:Cmic and CO<sub>2</sub>-C:Cext ratios. Among the tested enzymes involved in the C cycle, β-cellobiohydrolase, α-glucosidase, and β-xylosidase activities have shown a significant increase between treated and CTR soils in the latest samplings carried out.

The results of this 2-year field experiment would indicate that the physical and chemical properties of the soil did not change significantly after the HDPE particle addition, while the activity and abundance of the microbial community seem to be affected by the presence of microplastics.

Microplastics (MPs) accumulation is recognized as one of the main environmental issues in terrestrial ecosystems and in soil, which is considered the largest global pool of MPs. However, scientific evidence on the abundance, distribution and characteristics of MPs in soil are still insufficient, particularly in forest soils, which are less investigated by far than agricultural and horticultural sites. Mediterranean forests frequently experience wildfires; therefore, MPs deposited on the forest floor are likely to be subject to them. MPs subjected to high temperatures may be combusted and fragmented into smaller pieces. Furthermore, thermal processes can change the properties of plastics that may react differently within soil matrix.

This study aims to evaluate the effect of fire burning on the mass loss and composition of MPs particles (<5 mm) lying on the forest soil surface. To this end, we simulated several fires under controlled conditions by placing 10 plastics polymers, different in composition or shape, inside metal meshes placed under the litter of a typical Mediterranean pine forest. The residual ashes were further analyzed using 10 different techniques to find the most promising digestion and separation methods to isolate MPs.

The results showed that some polymers and shapes were more sensitive to fire. Polyethylene terephthalate (PET) pellets lost over 70% of their mass, while polyethylene (PE) pellet and fibers lost 59% and 75% of their mass, respectively. The greatest resistance to combustion was showed by styrene-butadiene rubber (SBR), which lost 27% of its mass. The second step of the experiment aimed to assess how much of the polymers were combusted and how much was fragmented into ash. However, none of the methodologies used were sufficiently effective in isolating the MPs as the organic fraction of soil interfered with both the density separation and oxidation techniques. In conclusion, wildfire could be both a driver in the MPs removal from soil and/or a driver of MPs spreading into smaller particles within the soil matrix.

**DOES THE PRESENCE OF MICROPLASTICS IN SOIL INCREASES THE UPTAKE OF INORGANIC POLLUTANTS BY CROP PLANTS?**

A. MEDYNSKA-JURASZEK, B. JADHAV

Wroclaw University of Environmental and Life Sciences, Wroclaw, POLAND

As one of emerging contaminants, microplastics (MPs) can enter the environment and adsorb toxic compounds thereby causing potential environmental and health risks. One of the concerns about microplastic presence in soil is that MPs can act as vectors of heavy metals modifying their mobility and bioavailability to soil organisms and plants. Due to increasing deposition of plastic into the environment the risk related to presence of microplastic and its impact on crop quality and yields should not be omitted. In the present study we investigated the interaction between four types plastic wastes found in the soils as microplastics (fibers, glitters, fragmented plastic bottles and plastic bags) on the uptake and accumulation of six potentially toxic elements (Cd, Co, Zn, Cu, As, Pb) by lettuce (*Lactuca sativa* L.). Soil for the experiment was collected from 50-100 cm depth, from the area of the copper smelter in SW Poland. Research was conducted under controlled conditions in the phytotron to minimize the risk of additional soil and plant pollution from air. Results of the study showed a very diverse effect of microplastics presence in soil on heavy metal uptake by lettuce. The effect depended on MPs' form. The presence of smaller particles like glitter and fiber (~1mm) had a greater impact compared to larger microplastic fragments derived from plastic bottles and bags, more often indicated in increased/decreased uptake of the tested metals. The effect also depended on metal e.g. for Cu indicated content in lettuce was lower when MPs was present in soil, opposite for Pb, Cd and As showing increase of metal(oid) content in plants. Moreover microplastic presence had greater impact on the root system and more significant changes were observed for the root zone, suggesting that MPs presence in soil may bring a bigger risk of root crops contamination.

### NEW APPROACH TO DESIGN DISASTER RISK MANAGEMENT POLICY OF DEBRIS FLOW AND FLASH FLOOD IN THE MOUNTAIN REGION

Y. LEI<sup>1</sup>, S.N. WU<sup>2</sup>

<sup>1</sup> Institute of Mountain Hazards and Environments, Chengdu, CHINA

<sup>2</sup> Chongqing Academy of Governance, Chongqing, CHINA

Debris flow is one of the most problematic soil-related hazards that could lead to catastrophic events when they occur near human settlements. Various DRR (disaster risk reduction) policies have been set up to reduce its negative impact. However, DRR policy design and implementation lack an evidence-based evaluation process. This study aimed to evaluate the effectiveness of some of the most adopted DRR policies, including setting up early warning systems, constructing disaster shelters, and providing incentives for evacuation. A policy evaluation model was developed by integrating debris flow processes and human behavior by coupling Flo-2d with agent-based modeling (ABM). The model was calibrated to simulate the DRR policy implementation in a real debris flow event in China. The main findings are: 1) setting up an early warning system was the most effective measure and fundamental of community-based disaster risk management as the system had contributed to a 30.06% casualties reduction in this case; 2) individual perception of DRR policies was at large variance which influenced the policy effectiveness; 3) marginal benefits of policies to raise public willingness might decrease quickly. Therefore, individual perceptions and behaviors significantly impact the effectiveness of DRR. This study provided an evidence-based approach to the policy-makers to formulate the most cost-effective DRR policies.

#### MULTIDISCIPLINARY STUDY OF SOIL FEATURES AS POTENTIAL TRIGGERING FACTORS OF SHALLOW LANDSLIDES. A CASE STUDY IN CENTRAL CALABRIA, SOUTHERN ITALY

F. SCARCIGLIA<sup>1</sup>, M. CONFORTI<sup>2</sup>, L. BORRELLI<sup>2</sup>, M. CIURLEO<sup>2</sup>, G. COFONE<sup>2</sup>, M. MERCURI<sup>2</sup>, A. GIOIA<sup>1</sup>, G. GULLÀ<sup>2</sup>

<sup>1</sup> Dipartimento di Biologia, Ecologia e Scienze della Terra (DiBEST), Università della Calabria, Rende (CS), ITALY

<sup>2</sup> Istituto di Ricerca per la Protezione Idrogeologica, Consiglio Nazionale delle Ricerche (CNR-IRPI), Rende (CS), ITALY

In this work we aimed at assessing whether and how key soil properties may act as control factors of shallow landslides (flows and complex slumps/slides-flows) on marly and silty clay terrains of a stream catchment in Calabria, southern Italy. We applied a multidisciplinary methodological approach, including geological, geomorphological, pedological and geophysical surveys, drone acquisition of relief features, multitemporal analysis of satellite images, mapping of major landslides occurred during the last twenty years using GIS, morphological field description and horizon-wise sampling of representative soil profiles for subsequent laboratory analyses. Laboratory activities included traditional pedological analyses for the determination of physical and chemical soil properties (particle size distribution, organic and inorganic carbon, pH, electrical conductivity, cation exchange capacity, exchangeable bases, soluble salts, clay mineralogy), coupled with some geotechnical analyses (bulk density, specific gravity, total porosity, Atterberg limits). The soils of the study area are Regosols and Calcisols, in places showing stagnic properties (due to transient waterlogging conditions) or protovertic properties (caused by cyclical shrink-swell dynamics). They are poorly developed soils, truncated by water-driven erosion and shallow landslides, as confirmed by the lack of surface A horizons, dominance of BC and CB horizons, low organic matter content, alkaline to strongly alkaline soil reaction. The liquid limit was mostly in the range of 40-60% and the plasticity index between 10%-20%, which are consistent with a dominance of illite, kaolinite and/or smectite clay minerals, and occasionally traces of chlorite or vermiculite. Based on the values of soluble salts and exchangeable bases, where Ca or Na cations prevailed, the sodium adsorption ratio and the exchangeable sodium percentage were calculated and used as indicators of clay dispersivity. They interestingly showed higher values in deep horizons than in corresponding topsoils (similar to other chemical and rheological properties), suggesting that such subsoil layers might have been affected by an easier mobilization directly caused by their higher dispersive, liquid, and plastic behavior, thus leading to the triggering of shallow landslides.

#### SHALLOW LANDSLIDING OF ABANDONED AGRICULTURAL TERRACES

M. NICULITA <sup>1</sup>, M. MARGARINT <sup>1</sup>, N. NECULA <sup>2</sup>

<sup>1</sup> Department of Geography, Alexandru Ioan Cuza University, Iasi, ROMANIA

<sup>2</sup> Tulnici Research Station, Alexandru Ioan Cuza University, Tulnici, ROMANIA

Agricultural terraces in the form of cut-off ditches, hillside ditches, intermittent terraces, bench terraces, broad-based terraces, vineyards, and orchard terraces, were built to protect steep sloping lands against soil erosion and produce soil and drainage conditions for vegetation. Historically these modifications were the ones that provided one of the most consistent soil conservation measures on extended areas. In the Moldavian Plateau, Northwestern Romania, these agricultural terraces were built extensively after 1950, especially in the low hilly areas, as the main soil conservation measure. After 1990 these agricultural terraces were abandoned, not being maintained anymore, very often with their land cover changed to pasture. Although the national regulation did not allow their construction over landslide areas, there are many areas where these terraces were built over old or recent, small or big landslides. We investigated using old aerial imagery and LiDAR data the landslides that appeared after terrace construction and we tested several scenarios regarding their triggering. Because the agricultural terraces are shallow, also the landslides are predominantly shallow, and their density is higher for the areas where the terraces were built over previous landslides. The unavailability of multitemporal historical aerial imagery does not allow us to build a multi-temporal landslide inventory and establish if there are temporal frames when the frequency of landsliding was higher. In the context in which these landslides were predominantly triggered by rainfall events that generated water saturation in the shallow layer of disturbed material used for terrace building, we also used numerical modeling for establishing rainfall thresholds that will be tested in the future. At the present level of knowledge about the shallow landsliding of agricultural terraces, we show that the hot spots are represented by the abandoned terraces built over older big landslides.

**HYDROGEOLOGICAL CHARACTERIZATION OF VINEYARD STEEP SLOPES THROUGH A MULTIDISCIPLINARY SURVEY, FOR SHALLOW LANDSLIDES SUSCEPTIBILITY ESTIMATION.**

V. VIVALDI, M. BORDONI, P. TORRESE, M. CROZI, C. MEISINA

Department of Earth and Environmental Sciences - University of Pavia, Pavia, ITALY

Vineyards cultivated in steep terrains are widespread all over the world and they are the main landscape element as well as the main economic activity of many territories. Steep vineyards can be affected by several problems, as well as shallow slope instabilities, triggered by very intense thunderstorms or prolonged rainy periods. Shallow landslides can provoke severe damages to vineyards, leading to a general loss of fertility and biodiversity in the soil horizons. A characterization of the slopes where vineyards are cultivated becomes fundamental, in order to assess potential unstable conditions and to better understand the possible effects of different inter-row managements, in the probability of occurrence of slope instabilities. The aim of this work is to present a multidisciplinary method for shallow slope instabilities susceptibility estimation in steep terrain vineyards, performed following different steps: i) preliminary characterization of the slope geological, geomorphological and hydrogeological settings through UAV surveys, electrical resistivity tomography, soil trenches and soil water content monitoring ; ii) assessment of grapevine root density and reinforcement in inter-rows with different soil management (e.g. conventional tillage or sustainable solutions); iii) application of a simplified probabilistic model for the assessment of the probability of occurrence of shallow slope instabilities in correspondence of different soil managements. This approach was applied in different test-sites located in Oltrepò Pavese and Piacenza Province (northern Italian Apennines), two important Italian wine districts very prone to water stress and slope instabilities. The results of this work can allow to recognize conditions leading to shallow failures in vineyards cultivated in steep terrains, highlighting the positive role of soil managements.

This conference abstract is part of the project NODES which has received funding from the MUR – M4C2 1.5 of PNRR funded by the European Union - NextGenerationEU (Grant agreement no. ECS00000036).

#### 5.01 133614 - Soil needs in industrial agriculture and highly populated areas

##### FERTILISING POTENTIAL OF DRIED ANAEROBIC DIGESTATE FROM SLAUGHTERHOUSE BY-PRODUCTS

A. CIURLI, G. DI BIASE, S. RAPISARDA, C. CIAVATTA, L. CAVANI

Dept. of Agricultural and Food Sciences, Alma Mater Studiorum University of Bologna, Bologna, ITALY

Circular economy models aim at minimizing the resource consumption through recycling, remanufacturing and reusing materials. Thus, converting biodegradable organic wastes into renewable energy would keep the highest utility and value of the productive processes. The slaughterhouse and meat industry are worldwide rapidly growing and generate billions of tons of biological wastes annually. These excess materials can be used to produce biogas in digesters and the resulting anaerobic digestate represent a potential source of organic carbon and nutrients that could be applied to the soil as organic fertiliser.

The present work aimed to evaluate the fertilising potential of a dried anaerobic digestate (DD) produced from beef slaughtering waste. DD was firstly characterized and compared with other organic fertilisers, indicating its potential application to the soil. Further, a short-term soil incubation experiment was performed on two different soils, with a dose based on 100 mg/kg of nitrogen (N) for each fertiliser. After the incubation DD released 10-26% of their total N and 13-16% of total phosphorus (P), with different kinetics depending on the soil that had different physico-chemical characteristics and responded differently to the treatments. Biochemical indicators such as extractable carbon (C) and N, microbial biomass C(MBC) and enzymatic activities were analysed after the incubation. DD increased extractable N of 20-30% in each soil, more than the other organic fertilisers even with minor effects on extractable C or MBC. However, DD also increased chitinase and phosphatase activity, indicating a stimulated microbial activity regarding N and P cycling. Moreover, the presence of recalcitrant C forms, in spite of soluble C, indicated the higher stability of DD after digestion instead of the other organic fertilisers.

These findings suggested a positive effect on the soil fertility of DD application, raising the concrete possibility to use these by-products as organic fertilisers. Moreover, this work states that the characterization and the evaluation of chemical and biochemical soil parameters would allow the prolific recycle of slaughterhouse by-products.

##### BIOCHAR AND CAMELINA SATIVA (L. CRANTZ) IN MARGINAL LAND FOR LOW-ILUC BIOFUEL PRODUCTION

T. BARSALI <sup>1</sup>, F. TOZZI <sup>1</sup>, D. CASINI <sup>1</sup>, S. SANTARELLI <sup>1</sup>, D. CHIARAMONTI <sup>1,2</sup>

<sup>1</sup> RE-CORD, FIRENZE, ITALY

<sup>2</sup> POLITECNICO DI TORINO - DENERG, TORINO, ITALY

Biochar is recognized as a sustainable agricultural management practice by the EC Implementing Regulation 2022/996 on low-ILUC requirements for sustainable biofuels. In this experiment, biochar was used as a soil amendment (alone or mixed with compost) for the cultivation of Camelina (*Camelina sativa* L. Crantz), a promising alternative crop for sustainable oil production, well adapted to grow under low rainfall and in marginal soils. Hence, the combination of Camelina and biochar presents several desirable traits for deployment in regions prone to desertification.

The experimental design involved the comparison of different treatments, in 2 locations: i) only biochar (3 ton/ha) (BC); ii) only compost (20 ton/ha) (CO); iii) compost (20 ton/ha) + biochar (3 ton/ha) (BCCO); iv) only NPK fertilizer (133 kg/ha) (NPK); v) control treatment (without fertilizer or amendment) (CNT). All plots except CNT were equally fertilized with NPK (with 133 kg/ha).

The effect of soil amendments varied depending on the location. In Location 1, an improvement in physical characteristics (bulk density, porosity, and water availability) was observed in plots amended with biochar-based treatments. Also, despite the low nitrogen introduced in the BC treatment, soil solution explored by plant roots in these plots was richer in nitrates, suggesting a lower nitrogen leaching rate.

The highest seed yields were obtained in the presence of the biochar and compost mix (BCCO) for both varieties in the two locations (Figure 1). In detail, the use of biochar and compost produced an increase in seed yield of 54% and 34% at locations 1 and 2, respectively, compared to all other treatments.

These results show that 3 tons/ha of biochar (with mineral fertilization) may be sufficient for enhanced seed and oil yields compared to the use of 20 tons/ha of compost, especially in fields characterized by light and sandy soil.

Therefore, it is crucial to optimize the biochar usage protocol (alone or in combination with compost), considering soil initial characteristics.

##### **SURPLUS SOILS: REALISING BENEFICIAL CHARACTERISTICS TO ENABLE SUSTAINABLE REUSE**

H. THOMPSON-MORRISON, J. CAVANAGH, R. SIMCOCK, G. HARMSWORTH

Manaaki Whenua - Landcare Research, Lincoln, NEW ZEALAND

We defined 'surplus soils' as soils that have been disturbed through land and infrastructure development or natural processes (e.g. slips, silt/sediment), and are unable to be beneficially reused on-site. In New Zealand, these soils are often 'lightly contaminated', meaning contaminant (namely trace element) concentrations exceed background soil concentrations, but are below applicable human health or environmental protection thresholds. These soils present a low risk to human health and environmental quality, although their reuse is challenged by current regulations, and a lack of data on their nature and quantity. Surplus soils management in New Zealand currently has a lack of soil science/scientist involvement. Instead, management is dominated by geotechnical and contaminated land practitioners. Consequently, onsite use and reuse considerations typically focus on structural qualities and contaminants, and overlook many beneficial characteristics of these soils. As a result, most surplus soils are disposed of in landfill without consideration of opportunities to minimise their generation or beneficial reuse, leading to negative environmental outcomes and incurring high disposal costs. Drawing on international examples of sustainable management of 'surplus' or 'excess' soils, we have produced a guidance document that recommends steps to improve management of these soils. At the heart of the recommendations presented are the needs for enhanced soil science input, and the incorporation of te ao Maori (indigenous) perspectives, into surplus soils management. Practical next steps include filling information gaps on surplus soils being generated, establishing principles for a surplus soil sustainable management framework, and addressing regulatory and logistical challenges associated with the sustainable management of these soils. Ultimately, urban soils hold cultural and productive/life-supporting values that are currently not recognised, and consideration of soil resources is absent from current land and infrastructure development processes. Redesigning and rethinking current design and development pathways, adopting a circular economy approach, would lead to improved outcomes for both stakeholders and environmental quality.

RESTORING SOILS WITH ORGANIC SOIL AMENDMENTS; A CASE STUDY IN GEITASANDUR, SOUTH ICELAND.

P. GUPTA

University of Iceland, Reykjavik, ICELAND

Soil is a limited global resource, and it is threatened by anthropogenic activities like erosion, infertility from excessive use of chemical fertilizers and desertification that is amplified by climate change. This research analysed soils and subsequent data from a revegetation study by the Soil Conservation Service of Iceland and aimed to address the effects of various soil amendments on soil properties and vegetation cover. Four organic soil amendments including municipal waste, bokashi, chicken manure, and bonemeal were compared to two application rates of chemical fertilizers and a control. Methods involved i) analysis of soil samples for pH, soil organic matter, C/N, and available carbon; ii) vegetation surveys measuring vegetation height and vegetation cover in 2021 and 2022; and iii) a tea-bag index study to investigate decomposition rates in soil. Soil pH was significantly higher in bonemeal plots than in plots where higher dose of chemical fertilizer was applied. For 2021, grass cover and vegetation height were significantly greater in chemical fertilizer plots than the control. Two years post application (2022), vegetation cover was significantly higher for plots with chemical fertilizer, bonemeal, and chicken manure than the control. Decomposition rates did not vary among the treatments, but the litter stabilisation factor was significantly higher for chicken manure than in the control and bokashi plots. Organic soil amendments like chicken manure and bonemeal can be alternatives to chemical fertilizers. This study is an important step for reducing waste and achieving circular economy by restoring soils using locally sourced organic soil amendments.

##### SOIL MAPPING WITH A LIMITED NUMBER OF SAMPLES BY COUPLING EMI AND NIR SPECTROSCOPY IN HAZELNUT TREE ORCHARD

L. PACE, S. PRIORI, M. ZANINI, V. CRISTOFORI

University of Tuscia, Department of Agriculture and Forest Sciences, Viterbo, ITALY

Precision agriculture relies on high-detail soil maps to optimize resource use. Traditional soil proximal mapping methods, such as EMI sensing, require a certain number of soil sampling and laboratory analyses to predict maps of soil characteristics. VIS-NIR and NIR diffuse reflectance spectroscopy offer rapid and low-cost alternatives, allowing for increased datapoints and better map prediction accuracy.

The aim of this work is to test and optimize a methodology for high-detail soil mapping in a hazelnut grove of approximately 4 ha, located in Corte Migliorina farm (Southern Tuscany, Italy), using both EMI proximal sensor and NIR handheld spectrometer. The maps of ECa obtained by EMI provided the pattern of soil spatial variability. Only 5 topsoil samples (Ap horizon, 0-30 cm) were collected for laboratory analysis, following the maximum variability of ECa and elevation. In addition, other 40 topsoil samples (0-30 cm) were collected by a regular grid and used for NIR spectroscopy to increase the number of datapoints within the study field.

The spectrometer used for this work was the Neospectra Scanner (Si-Ware Systems, Menlo Park, USA), a low-cost NIR spectrometer (1350-2500 nm) based on MEMS (micro-electromechanical systems) technology.

Partial Least Square Regression (PLSR) using a national spectral library, augmented by the 5 local samples analyzed, was used to predict clay, sand, organic carbon (SOC), total nitrogen (TN), and cation exchange capacity (CEC). The 40 datapoints with predicted soil variables were used for spatial interpolation, using ECa map, elevation, and DEM derivatives as covariates. Two methods of interpolation were tested: Universal Kriging (UK) and Regression Kriging (RK). The errors of predictive maps were calculated by 5 additional points analyzed by conventional laboratory analysis. RK and UK showed similar accuracy, with lower prediction errors for SOC and clay ( $R^2 > 0.8$ ) and slightly lower for TN ( $R^2 > 0.5$ ). Low accuracy was calculated for sand and CEC mapping.

##### CAPSURE VS SCIENTISTS: SOIL COLOR IN HUMAN PERCEPTION AND AUTOMATIC DEVICE RECOGNITION

K MILEWSKA <sup>1</sup>, M SWITONIAK <sup>2</sup>

<sup>1</sup> Doctoral School of Exact and Natural Sciences, Nicolaus Copernicus University, Torun, POLAND

<sup>2</sup> Faculty of Earth Sciences and Spatial Management, Nicolaus Copernicus University, Torun, POLAND

The development of remote sensing technologies started a new stage of research on the diversity of soil cover on a local scale. Low-altitude photogrammetry carried out with unmanned aerial vehicles (UAV) is a modern attempt to determine the extent and degree of erosional alteration of soil cover based on soil color and landform.

The study focuses on the color of soil samples of surface horizons of soils from young glacial areas of northern Poland and aims to compare the classical manual soil color tests, the results obtained from orthophotomaps and the tests of soil samples in the laboratory conditions using the Munsell CAPSURE Color Matching Tool Portable Spectrocolorimeter which automatically determines the color of a given surface. Presented results are intended to compare the possibilities of soil color determination, their validity and objectivity.

Determination of colors according to the Munsell Scale has so far been carried out manually, which involves the risk of error due to subjective feelings towards the color. In addition, the color measurement is influenced by the light source (natural - the angle of incidence of sunlight, artificial - the power and shade of light), air pollution and other weather condition. The study aims to check the variability of color perception among employees and students of universities with varying degrees of soil science knowledge. The color of identical soil samples was determined by professors, doctoral students and groups of first-cycle students.

Implementation of the CAPSURE device on an academic scale requires a series of tests to establish the compliance (or non-compliance) of the obtained results with field measurements, determination of the soil color in a subjective manner and calculation of the pixel colors of a given resolution on the orthophotomap. Comparing the results of soil color from three different sources involving CAPSURE device is an innovative approach to research on soil color and soil properties.

**Keywords:** soil color, soil erosion, soil spectrocolorimeter, UAV photogrammetry, Munsell CAPSURE

PREDICTING SOIL FERTILITY WITH INTEGRATED USB MICROSCOPE-BASED SOIL IMAGING, AUXILIARY FACTORS, AND PORTABLE X-RAY FLUORESCENCE SPECTROMETRY

S CHAKRABORTY <sup>1</sup>, S DASGUPTA <sup>1</sup>, D WEINDORF <sup>2</sup>

<sup>1</sup> INDIAN INSTITUTE OF TECHNOLOGY KHARAGPUR, KHARAGPUR, INDIA

<sup>2</sup> GEORGIA SOUTHERN UNIVERSITY, STATESBORO, USA

The potential of portable X-ray fluorescence (PXRF) spectrometry sensor for rapid assessment of plant-available soil nutrients remains underexplored, as critical parameters like organic carbon (OC), available S, available B, and sulfur availability index (SAI) cannot be directly measured by PXRF. In contrast, soil image analysis has mainly focused on differentiation of soil texture and organic matter. This study encompassed 1133 samples across Eastern India's diverse agro-climatic zones, and utilized the combined power of color and image texture features from USB microscopic soil images (IFs), PXRF data, and auxiliary soil variables (AVs), deploying random forest (RF) modeling to predict five important soil fertility parameters (OC, available S, available B, available Mn, and SAI). In total, 231 IFs were extracted, comprising 204 textural and 27 color features. Textural features were extracted from the gray level co-occurrence matrix and gray level run-length matrix of individual color channels [Red (R), Green (G), and Blue(B)] while color features were derived from the hue, saturation, and value (HSV) and L\*a\*b\* color spaces, along with RGB images, yielding mean, median, and standard deviation values for each channel. Principal component analysis revealed links between soil color variables, agro-climatic zones, and parent materials. Notably, integrating AVs with IFs greatly improved prediction accuracy, as demonstrated by robust R<sup>2</sup> values of approximately 0.80 for available B and 0.88 for OC. Available Mn and SAI benefited from a data fusion approach (IFs + AVs + PXRF), yielding R<sup>2</sup> values of 0.72 and 0.70, respectively. The correlation between residuals of RF predictions using (IFs + AVs) and RF-predicted values from PXRF data alone indicated improved prediction results, especially for available Mn. These findings underscored the potential of this proposed approach for rapid soil testing, offering cost-effective alternatives to traditional analyses and promising advances in soil health and fertility understanding.

##### RAPID AND COST-EFFECTIVE SOIL ELEMENTAL ASSESSMENT USING NIX PRO COLOR SENSOR

G JHA <sup>1</sup>, D SIHI <sup>2</sup>, B DARI <sup>3</sup>, M NOCCO <sup>4</sup>, A ULERY <sup>5</sup>

<sup>2</sup> Emory University, Atlanta, USA

<sup>3</sup> North Carolina Agricultural and Technical State University, Greensboro, USA

<sup>4</sup> University of Wisconsin, Madison, USA

<sup>5</sup> New Mexico State University, Las Cruces, USA

This study explores a rapid and economical approach to assess soil elemental content utilizing the Nix Pro colorimetric sensor. The research involved collecting representative soil samples from diverse agricultural fields within the Southwestern USA (New Mexico), establishing and validating predictive models for soil iron content. The Nix Pro color sensor, known for its cost-effectiveness, was employed in conjunction with color space models to create three distinctive parameter sets for iron prediction. The investigation resulted in the development of three new predictive models for soil iron content, with each model based on a different color space representation—CIELab, RGB, and CMYK. These models were compared against lab-based inductively coupled plasma analysis of iron content. Key performance metrics, including the coefficient of determination, root mean square error, and model p-value, were used to assess the predictive capabilities of each model. Notably, the CIELab, RGB, and CMYK models exhibited significance in predicting iron content, achieving coefficient of determination values ranging from 0.79 to 0.81. To validate the models, mean square prediction error (MSPE) and Kling–Gupta efficiency (KGE) Index were computed. The CMYK model emerged as the superior performer, with an MSPE of 0.13 and a KGE of 0.601, surpassing the CIELab and RGB models. The findings underscore the efficacy in rapidly and inexpensively predicting soil total iron content using NixPro. The use of colorimetric variables, especially with the CMYK model, highlights the potential for practical applications in soil analysis. The research contributes for generic investigations into soil properties, demonstrating the broader implications of this cost-effective technology in the field of soil assessment.

##### ADAPTATION OF VEGETATION INDICES FOR VINEYARDS USING REMOTE SENSING AND GROUND-TRUTH MEASUREMENTS

T ZSIGMOND<sup>1, 2, 3</sup>, A HOREL<sup>1, 2</sup>

<sup>1</sup> Institute for Soil Sciences, HUN-REN Centre for Agricultural Research, Budapest, HUNGARY

<sup>2</sup> National Laboratory for Water Science and Water Security, Institute for Soil Sciences, HUN-REN Centre for Agricultural R, Budapest, HUNGARY

<sup>3</sup> Doctoral School of Environmental Sciences, Loránd Eötvös University, Budapest, HUNGARY

Vegetation indices from remote sensing provide rapid and diverse information on the health and condition of vegetation. The aim of the present study was to investigate the usability of vegetation indices for vineyards while using ground-truth measurements for comparisons. The study sites were two vineyards one with silt loam (BCS) and one with clay soil texture (GB), located on 8-15% angled slopes in a small agricultural catchment in Balaton Upland, Hungary. Both vineyards were covered with perennial grass between rows.

The field monitoring system worked in 2020 and 2021. The monitoring system collected Soil Water Content (SWC), Normalized Difference Vegetation Index (NDVI), Photochemical Reflectance Index (PRI), and Photosynthetically Active Radiation (PAR) data at the upper and lower positions of both vineyard slopes. Leaf Area Index (LAI) was measured every two weeks during the vegetation periods. Concurrently with the field measurements we collected spectral data from Sentinel-2 (S2) and used to calculate different spectral indices.

The two different vineyard sites with grass inter-row allow us to compare the applicability of the vegetation indices. A moderately strong correlation was found between NDVI of field measurement and satellite NDVI ( $r=0.62$ ). We found a stronger correlation between different sources of NDVI data for BCS than GB. Both sources of NDVI were significantly different for GB and BCS samples ( $p<0.05$ ). PRI values for all study sites were weakly correlated, while LAI showed a moderate correlation with Red Edge bands in GB measurement points. SWC data was significantly different for GB and BCS ( $p<0.05$ ). Overall, we found that the reliability of vegetation indices can be significantly improved by regular ground-truth measurements.

**Acknowledgments:** This material is based upon work supported by the Hungarian National Research Fund (OTKA/NKFI) project OTKA FK-131792. The research presented in the article was carried out within the framework of the Széchenyi Plan Plus program with the support of the RRF 2.3.1 21 2022 00008 project.

##### UNDERSTANDING WITHIN-FIELD NITROGEN USE EFFICIENCY VARIATION USING PROXIMAL SENSING, FIELD OBSERVATIONS, AND MACHINE LEARNING

K ADHIKARI, D R SMITH, C HAJDA

USDA-ARS, Grassland, Soil and Water Research Laboratory, Temple, USA

Nitrogen (N) fertilizer input is a major decision farmers make to boost their crop yield. A better understanding of N use efficiency (NUE) can help farmers reduce N loss and off-site environmental impacts, and potentially increase farm income. N-fertilizers and their crop yield response have been studied but less has been understood about within-field NUE variations. Our objectives were to (i) quantify grain protein content using a NIR spectrometer (ii) derive NUE using yield, grain protein, and field observations, (iii) map NUE using apparent electrical conductivity (ECa), topography, and machine learning, and (iv) divide the field into NUE zones for precision management decisions. The study was conducted in nine corn fields in Riesel, Texas in 2023. Corn yield and grain protein content were measured using a combine equipped with an NIR spectrometer to monitor grain protein content. NUE was calculated from grain yield and its N content, N-fertilization, and soil N observations. A random forest model was trained to predict NUE where ECa and terrain attributes were used as covariates, and the model was evaluated on 25% of data not used in model training. Each field was divided into four NUE zones using k-means clustering (Low, Low-mid, Mid-high, and High-efficiency zones) that could be used for site-specific N-management decisions. Corn yield and gross margin (revenue – input cost) from the zones were compared across fields and zones. The ECa and topography explained up to 57% of variations in NUE. The maps showed that the fields were highly variable in NUE. For example, almost all areas of the 6-12 field and >60% of the SW-16 field had Low NUE whereas, >75% area of the Y-10 had Mid-High to High NUE. We will test the usefulness of remote sensing data as predictors of NUE in the future. Results from this study will help farmers optimize N-applications for economic and environmental benefits.

##### DELINEATION OF PEATLAND AREAS BASED ON DRONE-BORNE RADIOMETRIC SURVEYS AND UNSUPERVISED LEARNING

D V ADETSU, A M BEUCHER, M H GREVE, T KOGANTI

Aarhus University, TJELE, DENMARK

Peatlands are carbon-rich landscapes that contain one-third of the global soil carbon (C) pool. Their capability to either sequester or release C into the atmosphere depending on the management practice, renders them important for climate action. Climate change mitigation efforts such as the rewetting of drained peatland areas are among key strategies to reduce CO<sub>2</sub> emissions globally. In Denmark, there is a national goal to reduce the Danish CO<sub>2</sub> emissions by 70% in 2030; this includes rewetting 100,000 ha of the peatlands drained earlier for agricultural production. However, accurate knowledge of the location and extent of peatland areas is necessary to accomplish this. Delineating peatland boundaries based on conventional mapping is not only laborious and time-consuming but may lead to inaccuracies due to lesser sample size. Optical sensors might perform well in some scenarios, but they fail especially in those peatlands which are covered by non-peat forming vegetation due to commercial crop production. Here, UAV-borne gamma-ray radiometric surveys may be useful for rapid, cost-effective, and accurate delineation of peatland areas due to the unique attenuation behavior of peat. In this study, we present preliminary results where we assessed the seasonal suitability of performing such surveys along with the influence of different survey heights and flight speeds. The radiometric data were clustered separately using the Density-based spatial clustering of applications with noise (DBSCAN) and the clustering results were validated with ground truth measurements of peat thickness. We show that accurate delineation of the peatland boundaries is possible at various flight altitudes with different line spacing and is more importantly season unspecific. The results have implication for proper C accounting and effective planning of peatland rewetting activities.

##### MAPPING OF DANISH PEATLANDS USING PROXIMAL SOIL SENSING

T KOGANTI, D.V. ADETSU, A BEUCHER, M.H. GREVE

Department of Agroecology, Aarhus University, Blichers Allé 20, Tjele, DENMARK

Peatlands are important Carbon (C) reserves and they provide a wide range of ecosystem services. Over the years, draining their water table to meet energy and agricultural needs has led to increased release of greenhouse gases (GHGs) and dissolved C loss contaminating potable water, thus turning them into C-sources. Globally, different initiatives are put forward to safeguard, properly manage, and restore the peatlands to reduce GHG emissions and enhance C sequestration. However, a comprehensive characterization of peat inventory providing details on the spatial extent, thickness, and water table levels is required to accomplish this. The conventional methods involving handheld probes and boreholes are labor-intensive and provide only localized and discrete measurements. Proximal soil sensing methods provide an effective alternative solution. In Denmark, we are testing the suitability of electromagnetic induction (EMI), ground penetrating radar (GPR), and gamma ray radiometric on-the-go methods across a variety of peatland types, especially for estimating peat thickness. Electrical resistance tomography is being used along dedicated transects for controlled experiments. While EMI proved superior in a minerotrophic fen, GPR provided unequivocal results in an ombrotrophic bog. Gamma-ray sensing is not only suitable for delineating the peatland boundaries but can provide insights into the peat thickness gradient. Our results suggest that no single technique is a silver bullet and the sensor choice should be based on the knowledge of the peatland type. If unsure, we recommend performing EMI surveys ahead of GPR surveys for optimal cost benefit. This is because EMI can also be very useful in predicting the GPR success rate. Future work entails developing fully drone-borne sensors for improving scale and accessibility.

##### MACHINE LEARNING APPROACH USING MULTIPLATFORM DATA FOR PRECISION AGRICULTURE SYSTEMS

A VITALE, C CUTANEO, M BUONANNO, A BONFANTE

CNR - ISAFOM, Portici (NA), ITALY

Within a vineyard, the intricate interplay between plant water status and soil variability shapes the vineyard's productivity and qualitative response. The soil's physical attributes, exhibiting heterogeneity both horizontally and vertically, influence the soil water balance, leading to non-uniform responses within the vineyard. Proximal sensing emerges as a valuable tool in gauging apparent soil electrical conductivity (ECa) throughout the growing season, providing insights into the nature of spatial variability. This information not only facilitates viticultural microzoning, enabling the identification of Homogeneous and functional Homogeneous Zones (HZs and fHZs), but also supports field experiments.

We propose a machine learning approach that functions as a predictive model for soil ECa. This approach utilizes discrete measurements obtained from a network of Time Domain Reflectometry (TDR) probes, capable of quantifying ECa, to spatially predict ECa values across the surveyed area. The methodology enables the efficient management of resources and enhances crop productivity by providing farmers with a comprehensive understanding of soil conditions.

This approach was tested on Greco di Tufo grapevines (white) in southern Italy, employing a combination of data sources: soil and atmosphere system records, in-vivo plant monitoring of eco-physiological parameters in 2020 and 2021, and spatial variability of plant status monitored through UAV multispectral images. Apparent EC measurements were obtained using a PROFILER EMP 400 in both dipole modes and with three different frequencies (5, 10, and 15 kHz), enabling the exploration of various soil depths.

The predictive model exhibited remarkable performance, with results aligning well with existing knowledge of the area. This highlights the potential of this approach to revolutionize vineyard management practices, leading to improved resource utilization and enhanced crop yields.

Proximal soil sensors (PSS) are used to efficiently characterize soil properties from point to farm/field scale and reduce the need for cost- and labor-intensive soil sampling and laboratory analysis for creating high-resolution maps. They enable rapid means for soil characterization and monitoring of soil properties, providing tools to make informed decisions aiming at the improvement of productivity, soil health conservation, and mitigation of environmental impacts. A framework for selecting the most suitable PSS method for mapping a specific soil property based on expected accuracy and associated costs is lacking. Within the ProbeField project, we are reviewing the accuracy of electromagnetic PSS in estimating specific soil properties and quantifying associated costs. Moreover, we discuss cost and accuracy variation when using multiple techniques simultaneously. The lack of information on costs in the literature caused us to perform a market analysis through questionnaires directed to companies, a unique aspect of this study. Our review hopes to be a guide for professionals, academics, and other end-users in PSS.

We reviewed a total of 209 studies. The normalized root-mean-squared error (NRMSE) was used as a measure of accuracy in estimating soil properties. Among all, diffuse reflectance spectroscopy (DRS) and X-ray fluorescence (XRF) techniques exhibit higher accuracy in estimating soil carbon and nutrients, however, require soil sample contact. Gamma-ray radiometry and electromagnetic induction (EMI) are the most common on-the-go sensor combinations, especially used to accurately estimate water content and soil texture. The Cost of mapping services ranges between a few hundred to several thousand euros per working day depending on the technique and type of sensor used. About 75% of mapping cost is attributed to fieldwork personnel, and data analysis and reporting, while the other 25% is to movement efforts and sample analysis. Several companies report extra charges attributed to fieldwork conditions. Results demonstrate that portable sensors offer accurate and cheaper point estimations, although on-the-go sensors offer better spatial estimations at the expense of accuracy.

In-field soil spectroscopy represents a promising opportunity for fast soil analysis, allowing to predict several soil properties from one spectral reading representing one soil sample. This facilitates data acquisition from large amounts of samples through its rapidity and the absence of required chemical processing. This is particularly interesting in agriculture, where the chance to retrieve information from soils directly in the field is very appealing. This review focused on in-field visible to near infrared (Vis-NIR) spectroscopy (350-2500 nm), aiming at analyzing soils directly in the field through proximal sensing. The main scope was to explore the available knowledge, to identify existing gaps limiting in-field measurement reliability and robustness, to foster future research and help transition towards practical application of this technology. For this purpose, a literature review was performed evaluating the information about sensor range, used carrier platforms, sensor types, distance to the soil sample, measurement methodologies, target soil properties and soil management among others. A list of used tools with their spectral and measurement properties was produced, including the potential cross-calibration with soil spectral libraries from laboratory spectroscopy of soil samples and potentially measured soil properties. Different instruments and sensors are currently used to measure at varying wavelength ranges and with different spectral qualities, with a large range of prices. The most frequently analyzed soil properties included soil carbon contents (soil organic carbon, soil organic matter, total carbon), texture (clay, silt, sand), total nitrogen, pH and cation exchange capacity. Future perspectives comprise the implementation of larger databases, including different instruments and cropping systems as well as methodologies combining existing knowledge about laboratory spectroscopy with in-field methods. A broadly accepted measurement protocol for in-field spectroscopy, fostering harmonization and standardization, is necessary for a more robust practical application.

##### REORGANIZING SOIL DATASETS FOR DIGITAL SOIL MAPPING AND PRECISION FARMING PURPOSES: A STUDY CASE ABOUT DATA FUSION OF TWO PROXIMAL SENSORS

C LOZANO FONDÓN<sup>1</sup>, G L'ABATE<sup>1</sup>, R BARBETTI<sup>2</sup>, G VALBOA<sup>1</sup>, C BECAGLI<sup>1</sup>, I CRICUOLI<sup>3</sup>, L D'AVINO<sup>1</sup>

Precision agriculture often involves the use of publicly available data that has been collected for different purposes. The CREA Soil Archive Collection includes digital data and physical soil samples collected from multiple research projects, that allow the reuse of samples to generate added information and fulfill different objectives. Here, we present a case study about reorganizing a dataset of soil property data collected into specific research projects that were converted into quality-enough data to support DSM using data fusion obtained from proximal soil sensors (PSS).

Data were produced during four surveys between 2019 and 2022 in two farms located in Macerata, Italy. Campaigns consisted of georeferenced sampling at times t<sub>0</sub>, t<sub>2</sub>, and t<sub>3</sub>, and gamma-ray surveys (distributions for <sup>40</sup>K, <sup>232</sup>Th, <sup>238</sup>U isotopes and total count) at times t<sub>1</sub>, t<sub>2</sub> and t<sub>3</sub> of both sites. A total of 46 points were distributed and sampled in both sites (t<sub>0</sub>=14, t<sub>2</sub>=16, and t<sub>3</sub>=16 points). Laboratory analysis consisted of soil properties determination and collection of spectral data using a spectroradiometer. Aim of this work was to obtain plausible distributions of soil properties at time t<sub>1</sub> by using spectral and soil available data to perform statistical models, and spatialize the result using radionuclides as covariates: 1) Support Vector Machine (SVM) was applied to calibrate models for soil properties estimation; 2) principal components (PCs) of georeferenced spectral data were calculated and correlated with radionuclides point; 3) multiple linear regression analysis (MLRA) with PCs and maps of radionuclide were used to spatialize. SVM modeling threw accurate estimates for EC, pH, clay, and sand contents, while lower relationships were found for SOC and carbonates due to variation between sites. MLRAs' relationships with PCs were poor due to the small number of samples and high data noise. However, significant correlations were obtained. This represents new perspectives for generating plausible new data based on local models that would allow setting uncertainty thresholds for mapping soil properties.

##### MACHINE LEARNING BASED FOR PREDICTING IRON OXIDES IN SOIL B HORIZON FROM DIFFERENT TYPES OF SMARTPHONES

F. SHEN<sup>1</sup>, J. YANG<sup>2</sup>, T. WANG<sup>2</sup>, N. LI<sup>2</sup>, S. QUE<sup>2</sup>, Z. CHEN<sup>1</sup>

Iron oxides in the B horizon are key indicators of soil development, but traditional analysis methods like free iron oxide (Fed), total iron (Fet), and freeness of iron (Fed/Fet\*100%) are too time-consuming for modern smart agriculture. In contrast, smartphones as proximal sensors for acquiring soil color parameters present a more efficient approach in precision agriculture for predicting soil properties. However, their application in predicting iron oxide content, a key soil color determinant, is less explored. Furthermore, the significant variations in imaging characteristics among different smartphone models necessitate a thorough investigation for reliable soil analysis, especially iron oxides. This study aimed to assess various effectiveness in predicting iron oxide content in soil B horizon and understand imaging variability, we imaged 150 soil samples by using five smartphones. Subsequently, these samples were scanned with a hyperspectral imager to explore the modeling capabilities. Based on the obtained soil color parameters and spectral data, Support Vector Machine (SVM) and Partial Least Squares Regression (PLSR) were utilized to build the models to predict the iron oxides (Fed, Fet, Fed/Fet\*100%) content. Drawing on prior research, we analyzed spectral response curves from five smartphone cameras, uncovering that iron oxides in soil reduce brightness but increase redness, thus enhancing our understanding of smartphone imaging for soil analysis. The prediction outcomes using the five smartphones closely matched the model based on hyperspectral data, with Fet ( $R^2 = 0.57\sim 0.66$ , RMSE = 12.57~15.34 g/kg, RPD = 1.50~1.73) being better than Fed ( $R^2 = 0.51\sim 0.68$ , RMSE = 5.90~7.25 g/kg, RPD = 1.40~1.75). Comparative analysis of spectral response curves across smartphones revealed that models for iron oxide estimation were more accurate with devices exhibiting stronger spectral response and pronounced peaks in the R band. This study highlighted the viability of using various smartphones as soil sensors for iron oxide prediction, offering a theoretical guide for selecting the optimal device for accurate model development.

Substantial improvements of field robotics could provide large coverages in a more uniform matter. However, this mechanized standard cannot be considered optimized as mostly disregarding within-in field soil variations. Large cropping areas require detailed sampling approaches to consider and reconcile soil property differences for field interventions. To identify soil heterogeneous zones demands an optimized sampling approach. The objective was to integrate soil data from two proximal soil sensors to improve the delineation of homogeneous soil regions using a k-means clustering algorithm defining three distinct management zones in an irrigation pivot with 72 ha in Itaipá, São Paulo, Brazil. A regular sampling grid of one hectare was sampled for the attributes of CEC, V%, texture, organic carbon, and pH, as well as a second optimized sampling grid was guided by proximal soil sensor datasets. Maps of apparent electrical conductivity, apparent magnetic susceptibility, equivalent thorium, and equivalent uranium provided by two sensors were considered to guide this optimized sampling schema. These maps served as preliminary information using the spsann sampling algorithm in R. Six locations were defined for soil sampling in each of the three previously defined management zones. A dataset of 18 points collected at depths of 0–10 and 10–20 cm were subjected to analysis of variance, checking whether each zone could distinguish soil heterogeneities. Only clay, organic carbon, and calcium attributes showed significant differences between grids with 72 and 18 points at depths of 0–10 and 10–20 cm. The optimized approach shown that sensors information could improve management zone delineations, as identifying soil heterogeneities concerning clay texture and organic carbon content. The approach using sensor data and the spsann algorithm could promote a reduction of four times less sampling points, yet providing a more precise delineation of soil heterogeneities. It was observed that a very homogeneous spatial distribution of nutrient concentrations could not significantly contribute to delineate management zones.

Geophysical methods can be used to map soil properties and deduce understanding soil processes at spatial scales beyond what is possible with traditional monitoring techniques such as soil sampling. In managed grasslands, geophysical methods can be crucial to bridge the scale gap from point to field scale, and to allow for field-scale characterization of animal-induced soil compaction patterns affecting soil water dynamics and controlling nitrogen cycling. In this study, we explore how integrated modelling of grazing patterns, soil structure dynamics, soil processes and electromagnetic induction (EMI) data could provide insights of nitrous oxide (N<sub>2</sub>O) emissions in managed grasslands. This was achieved by using EMI data to calibrate soil structure properties (e.g., bulk density, macroporosity and hydraulic conductivity) in an agroecosystem modelling framework. This allows to associate patterns in EMI data with soil structure variations due to compaction and ultimately allows to make predictions of soil water and nitrogen dynamics that are consistent with such observations. This approach was tested using EMI data and management information from a dairy farm in central Ireland. The EMI-calibrated model predicts that N<sub>2</sub>O emissions from compacted zones (occupying about 20% of the total area) are 2.5 higher than those from non-compacted zones. This is consistent with profile-scale studies reported in the literature for compacted grasslands. Linking agricultural management and geophysical data through agroecosystem modelling offers new means for large-scale and long-term testing and monitoring of the environmental impacts of management for different agricultural systems. This modelling framework could be used in combination with EMI data to test different management systems to help minimizing N<sub>2</sub>O emissions in compacted grasslands.

Digital Soil Mapping (DSM) uses topographic characteristics and remote sensing data to map soil properties. Soil property maps are useful for soil fertility and health planning and management. Soil properties reflect soil dynamics and are used as diagnostic tools to describe past and current soil water status. However, in most cases the water dynamic characteristics used for soil classification are aggregated monthly and/or annually. Finer spatial and temporal characterization of soil water movement is needed to better understand the spatial distribution of soil properties and support management decisions at multiple scales from hillslope to watershed and regional. In this study we used a distributed soil vegetation hydrological model (DHSVM) to characterize soil water movement (soil moisture-SM and depth to saturation-WTD) at two hillslopes under pasture and forest vegetation. Modeled soil moisture was compared with sensor measured values at key slope positions (summit, sideslope and toeslope) and three depths. Temporal patterns of measured data matched those estimated by DHSVM. The positions of peaks and valleys between simulated and measured SM for both pasture and forest vegetation matched at depths 0-20 and 20-45 cm, as shown by the significant correlation coefficients that varied between 0.6 and 0.8, with values for the summit and toeslope being higher compared to sideslope. Fragipans observed in sampled transects in both pasture and forest hillslopes were found to be correlated with SM during summer and WTD during spring. The depth to C horizons showed the highest correlation for pasture ( $r = -0.3^*$ ) for the forested hillslope ( $r = 0.1^*$ ). The validated soil moisture maps and depth to saturation (WTD) can be used to predict soil properties spatially and temporally for research on soil pedogenesis and support precision agriculture applications.

Reliable measurements of soil moisture can contribute to sustainable management of water resources and to safeguarding crop yields and soil health under climate change. Within the framework of the EU H2020 project SOILGUARD, we examined the effects of simulated droughts and heatwaves on water storage in different biomes across 7 NUTS-2 regions, and under different management regimes, i.e., conventional vs. organic management in croplands, monoculture vs. species mixtures in grasslands, and clear-cut vs. continuous cover forests. TOMST® soil moisture sensors were installed in the plots of five croplands (Spain, Belgium, Denmark, Hungary, and Latvia), one grassland (Ireland), and one forest (Finland) site. Drought periods of 3 months were induced using on-field rainout shelters and heatwaves were simulated using infra-red heating panels run for 5 days. The data of all countries was aggregated by averaging reads every 12 h, and it was analyzed by linear mixed effects models. The simulated climate stressors had a clear effect on soil water content. Whereas forestry practices such as shelterwood cutting significantly improved soil water retention, the rest of the studied practices on croplands and grasslands didn't show clear differences in their capacity to resist climate stressors. Rainfall exclusion and the use of heaters were useful to simulate drought and heatwaves for soil moisture monitoring; furthermore, considering longer establishment times for organic practices may help differentiate more clearly between the type of management.

#### ASSESSING DANISH PEATLANDS OVER THE LAST DECADE: MAPPING AND INTERPRETING THE SPATIOTEMPORAL VARIATIONS OF SOIL ORGANIC CARBON STOCKS AT NATIONAL SCALE

A BEUCHER, P WEBER, C HERMANSEN, C PESCH, M GREVE

Aarhus University, Department of Agroecology, Tjele, DENMARK

In Denmark, drained agricultural peatlands contribute at least 10% to greenhouse gas emissions, and rewetting part of these areas will enable reducing the emissions. Optimal rewetting requires knowledge of hot spot emission areas for which rewetting may lead to the greatest reduction. Mapping soil organic carbon (SOC) stocks within Danish peatlands represents a first step towards the estimation of emission from these areas. A peatland soil database was generated from a national field survey carried out in 2009 and 2010. About 10,000 sites were visited and more than 20,000 soil samples were collected following a systematic sampling scheme with up to four subsamples taken at 30-cm depth increments at each sampling location. Recently, we revisited 1,000 sampling sites, which provided the unique opportunity to assess the variation in SOC stocks at different depths over a decade. The present study aimed at mapping and interpreting the variations in space and time of this key peat soil function at a national scale. A Cubist bootstrap modelling approach was employed using soil, geology, landscape, topography, climate, laboratory visible-near infrared spectra, Sentinel-1 and -2 data as predictors at a 10-m spatial resolution. The modelling method yielded both a mean prediction maps for SOC stocks at different depths and the associated uncertainty maps. The best-performing models were also analysed with a model-agnostic interpretation technique yielding crucial information for further use of the predictive map and enabling a better understanding of Danish peat soils.

#### MAPPING SYNERGIES AND TRADE-OFFS BETWEEN SOIL BIODIVERSITY AND ECOSYSTEM FUNCTIONS IN DANISH FORESTS

S KEPPER ROJAS, L D'IMPERIO, Y M ROSAS, B WANG

University of Copenhagen, copenhagen, DENMARK

Forests play a pivotal role in preserving biodiversity, mitigating climate change, and providing essential goods and services. In alignment with the European Biodiversity Strategy advocating for the strict protection of 10% of land area, the challenge lies in balancing these ecosystem services with societal demands for available land. This study focuses on optimizing land use planning to reconcile the multifunctionality of forests, emphasizing the critical role of forest soil in supporting biodiversity and ecological functions.

A comprehensive survey was conducted, sampling soils in approximately 320 plots from the National Forest Inventory of Denmark. This involved quantifying physicochemical properties, extracting environmental DNA (metabarcoding), and employing Ecoplates® for functional assays to construct profiles of soil communities. Additionally, soil incubation was performed to measure greenhouse gas fluxes.

The study integrates microbiome data to provide insights into the relationships between soil microbiomes and ecosystem functions. Leveraging the National Forest Inventory's comprehensive information on forest structure, dynamics, history, and composition, the research aims to map soil biodiversity including fungi, bacteria, and soil fauna.

Spatial prioritization analysis will be employed to generate spatially explicit maps of forest and soil functions, along with microbiome diversity. These maps will highlight areas of synergies and trade-offs, offering valuable insights for prioritizing regions to enhance forest multifunctionality. By bridging the gap between ecological research and practical landscape planning, this study contributes to the ongoing dialogue on sustainable forest management and biodiversity conservation.

##### Where to go next?

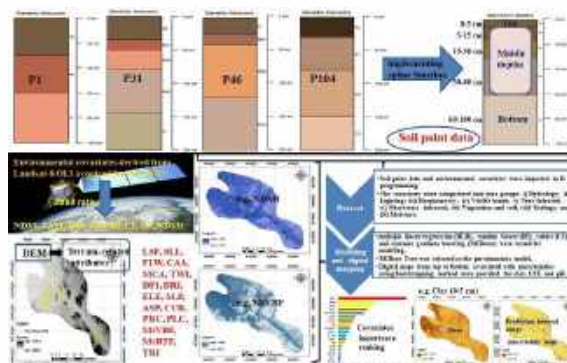

#### DIGITAL SOIL MAPPING FROM SCIENCE TO PRACTICE OVER THE PAST FIVE YEARS: LESSONS FROM NORTH-WESTERN IRAN

F SHAHBAZI <sup>1</sup>, B MINASNY <sup>2</sup>, A B MCBRATNEY <sup>2</sup>

<sup>1</sup> Soil Science Department, Faculty of Agriculture, University of Tabriz, Tabriz, IRAN, ISLAMIC REP

<sup>2</sup> Sydney Institute of Agriculture & School of Life and Environmental Sciences, The University of Sydney, Sydney, AUSTRALIA

Digital soil maps are a starting point for formulating soil science hypotheses. They are a complement to conventional soil maps. Digital soil mapping (DSM) is not simply exercises in themselves, but also facilitate understanding the distribution of soil properties. Most frequently studies beyond DSM belong to Australia and China, Brazil, the United States, France, Germany and Iran. There was an opportunity to apply DSM in Urmia Lake (north-western Iran). A location which was faced desiccation. Some important issues addressed as follows: I) Spatial variability of crystalline iron (doi:10.1016/j.geoderma.2018.11.024); II) Different iron forms and futures (doi:10.1016/j.geodrs.2020.e00275); III) Potentially toxic elements enrichment due to water-level decline (doi:10.1016/j.scitotenv.2021.152086); IV) Soil salt composition and ionic strength (doi:10.1016/j.rsase.2021.100498); and V) Soil chemical ripening process (doi:10.1016/j.catena.2023.107440). The aforementioned projects were performed using solely spectral data. The map uncertainty was successfully quantified by a bootstrapping method. Obviously, terrain-related attributes play an important role in DSM (doi:10.3390/agronomy12071653). Understanding the vertical distribution of agriculturally important nutrients (doi:10.1016/j.catena.2018.10.005) and some key soil properties at multiple standardized depths following the GlobalSoilMap project specifications is indispensable (doi:10.1111/sum.12900). In summary: I) Cubist, random forest (RF) and extreme gradient boosting (XGboost) tree models show high efficiency; II) The ripened soils have been established far from the water body of Urmia Lake; III) Crystalline iron is more sensitive to the visible bands compared to other iron forms and features; IV) The soils were enriched with As and Cu with more than 60% considered polluted across the east shore of Urmia Lake; V) The valence of ions played significant role in predictive mapping; VI) The geochemical indices demonstrated the transition from geogenesis to pedogenesis using DSM; VII) Regardless of soil subgroups, there was a decreasing trend of soil organic carbon storage (SOCS) with increasing depth; and VIII) Overall, the SOCS for an agricultural area of interest, normalized by area within soil order boundaries, was generally higher in Inceptisols (9.99 Tg) than in Aridisols (8.00 Tg).

<sup>4</sup> Geological Survey of Finland, Rovaniemi, FINLAND

One of the main challenges in digital soil mapping is the imbalanced datasets for soils classification. For these datasets, machine learning techniques use to overestimate the majority classes and underestimate the minority ones. This generates maps with poor precision and unrealistic results. Considering these maps for land use decision-making can have dire consequences. This is the case of acid sulfate (AS) soils, a harmful soil that can generate serious environmental damage when drained in agricultural or forestry activities. In the study area, the probability of finding AS soils is very high. Furthermore, some of the most hazardous AS soils in Finland are located there. Therefore, it is necessary to create high-precision maps to avoid environmental damage. Since the dataset for this region is highly imbalanced, the first step in creating accurate maps is to balance the dataset. Although most soil class datasets are imbalanced, this problem has been hardly studied. In this work, we analyze different techniques to address the problem of imbalanced datasets. The methods considered to balance the dataset are under- and oversampling techniques and the combination of both. For the oversampling of the minority class, we create a kind of artificial samples from the quaternary geological map. The method used for the modeling is Random Forest. Balancing the dataset improves the performance of the model in all the studied cases, where the values of the metrics for both classes are above 80%. Furthermore, we create AS soil probability maps for the four balanced datasets and the imbalanced dataset. A detailed comparison between the maps is made. Additionally, the extent of the AS soils obtained in all the cases is compared with the extent of the AS soils in the conventionally produced occurrence map. The modeled probability maps created from the balanced datasets have a high precision. The results of this study confirm the importance of balancing the dataset to improve the prediction and classification of AS soils.

<sup>5</sup> DHM Software, Toowoomba, AUSTRALIA

The spatial variation of crop yields within a field can arise from various reasons, but the primary driver is often the soil. Persistent spatial variation of crop growth is likely attributed to soil constraints. These factors contribute to yield losses for grain growers globally. The initial step in mitigating this yield gap involves identifying the soil constraint. A better understanding of historical spatial and temporal variation in crop yields can empower growers to make informed management decisions. To address this, we have developed a web-based tool, ConstraintID, designed to enable grain growers in the northeastern regions of Australia to identify consistent spatial patterns within their fields. The tool utilizes historical remote-sensing data from 1999 to the present, searching for consistent spatial patterns of the Crop Yield Index derived from Enhanced Vegetation Index (EVI) Landsat data around the peak EVI. To assess the tool's effectiveness, we sampled 121 fields across the region. Each field was divided into three zones (consistently poor, consistently good and inconsistent) using ConstraintID. A representative sample was taken for each zone (three cores split into five depths/zone), and analysed for a suite of soil properties. The data analysis presented here focuses on two key questions: (i) has remote-sensing analysis proven useful in identifying areas of constrained soil, and (ii) what soil constraints correlate with within-field variation in crop growth? The results indicate that the impacts of sodicity and salinity are evident through negative relationships between the growth zone and sodicity in surface soil, and salinity, and chloride in subsoil ( $p < 0.001$ ). This demonstrates the tool's effectiveness in identifying areas within fields with relatively poorer growth associated with variations in soil constraints. Additionally, strong associations were found between nutrients and growth zones. Soil carbon and potassium showed strong evidence of a positive association with growth zones ( $p < 0.001$ ). For soil nitrate N, there was strong evidence ( $p < 0.001$ ) of a negative association in subsoil.

In Switzerland, authorities must soon delineate areas for the high-quality arable land inventory based on high-resolution surveys that require sampling of large numbers of new locations. Consequently, efficient surveying strategies are required which fulfil high quality demands for legally binding decisions. These decisions require soil attributes which cannot only be derived by laboratory measurement but are based on pedological field description by experts.

In our study area of 1'000 hectares, we established first a feature space coverage sampling design to sample 1'500 locations based on elevation and land use data, geological information, and expert knowledge of soil scientists. 170 locations were determined by a stratified random sampling design and used for independent validation.

A first prediction of a large range of soil attributes in multiple depth using the first 1'200 samples, random forest, and a wide range of environmental covariates showed medium accuracy. Therefore, we increased the total number of sampling locations to 2'200 by two in-fill sampling design strategies in two zones:

1. Experienced surveyors directly added additional sampling locations based on their expert knowledge. Those covered landscape features which not contained in the primary sampling design such as local extrema or transition zones.
2. A complementary further covering feature space as spanned before and with a higher sampling density within zones of high model uncertainties.

Subsequently generated maps showed increased accuracy with increasing sampling density for most attributes, e.g., an increase of 0.1 for the clay content in the topsoil at a sampling density of 1.7 observations per ha compared to a density of 1.1. Our results further displayed increasing accuracy of 0.05 with higher-weighted data collected by experts and simultaneous lowering the sampling density to 1.5 per ha by ignoring data with the lowest quality, collected before the calibration of the field survey.

Additionally, we proposed applications derived from these maps for specific agricultural use to local farmers, like options for precision farming or planning bases for irrigation systems.

High-resolution reliable and quality-controlled soil information products are fundamental for a range of applications related to climate change and sustainable management. Integration of remote sensing information is a key strategy to obtain more accurate and relevant products.

Digital soil mapping (DSM) uses a statistical model to integrate products derived from Copernicus satellites Sentinel-1 and 2, environmental covariates such as digital elevation models, ERA-5 products and soil ground truth information from the LUCAS survey and other available sources. Several data products are derived from the Sentinel-2 time series using the Soil Composite Mapping Processor (SCMaP). It comprises mean reflectance composites as well as specific soil reflectance composites that contain undisturbed and bare soils. Additionally, the bare soil frequency is a measure for the visibility of the bare soil within the whole observed time period in percent. EO based soil products were generated for primary soil properties (SOC, pH, texture), derived soil properties and some basic soil health indicators. These properties were selected as a short list by scanning the current policy framework, existing projects and initiatives. In the second phase, users are approached by a survey and webinar to prioritise and specify the user needs for the shortlist, and to check for additional user needs and specifications. In total, 150 potential users have been reached so far. The soil observations were split in 10 equally sized folds for cross-validation. Random Forest models were obtained with the ranger package, with the option to build Quantile Random Forests (QRF) to obtain pixel-based uncertainty.

This contribution will discuss where to go from the generation of high resolution products with a sparse point data sampling such as LUCAS, to their evaluation (including landscape patterns), to their relevance of use for stakeholders. The results of a user requirement survey dedicated to future soil products within the Copernicus Land Monitoring Service will be taken into account into the discussion of the products and their fitness for use.

<sup>2</sup> IBF AGRONICA-JOLANDA DI SAVOIA, FERRARA, ITALY

<sup>3</sup> UNIVERSITY OF PADOVA, PADOVA, ITALY

High-detail soil mapping is fundamental to apply precision agriculture approaches. Although soil maps are available in many countries at a regional scale for land planning purposes, there is a need to increase the detail in the most important agricultural areas for application of site-specific agriculture practices and soil monitoring. New data from proximal and remote sensors, as well as quantitative digital methods provide the right tools to obtain these maps with sustainable costs. The limitation of using satellite images in soil mapping is the masking effects of the vegetation and the crop residues on the surface. To address these issues, multitemporal composite images of bare soil can be elaborated. The Synthetic Soil Image (SYSI) performed by the algorithm Geospatial Soil Sensing System - GEOS3, developed in Google Earth Engine, is an example of such a product. For this work, SYSI was created by applying GEOS3 on 394 Sentinel-2 satellite multispectral images (from 2017- February 2023).

This study aims at producing maps of topsoil characteristics, namely soil organic carbon (SOC), clay, sand, total nitrogen (TN), cation exchange capacity (CEC), and total carbonates (TCa) at local level (the Rieti agricultural plain, about 4,000 ha), using digital soil mapping methods combining punctual soil observations (94), Digital Elevation Model (DEM) and derivatives, and the four bands of SYSI (RGB and NIR).

A statistical correlation between soil variables and covariates shows that all the four bands of SYSI are highly and negatively correlated with clay, SOC, TN, and CEC, whereas are moderately and positively correlated to sand and TCa.

Two geostatistical methods were tested to spatialize soil parameters: i) universal kriging (UK) using all the covariates as trends; ii) regression kriging with stepwise regression (RK). An independent dataset of 11 soil samples was used to validate the spatialization. SYSI bands were found to be the most explanatory covariates for interpolating SOC, clay and sand with high accuracy.

<sup>6</sup> Council for Agricultural Research and Agricultural Economy Analysis (CREA), Firenze, ITALY

<sup>7</sup> Soil Geography and Landscape group, Wageningen University and Research, Wageningen, THE NETHERLANDS

The EJP SOIL project aims to provide the research and policy-making community with detailed and harmonised EU-wide thematic maps of agricultural soils, based on a common methodology, to improve the effectiveness of European agricultural and environmental policies, to contribute to European international reporting. Currently the national and the EU reporting are performed independently, which results in contrasting figures on soil status. Since national soil data sharing constraints are in place, a bottom-up approach is preferred to include as much relevant data as possible. However, this can in return, generate transboundary issues.

The specific objective of the EJP SOIL mapping exercise is to set-up a digital soil mapping procedure to: i) support participants in a bottom-up approach allowing countries to produce high-resolution thematic soil maps, ii) develop soil property maps based on the national databases (SIMS) and the LUCAS Topsoil database, iii) solve the problems of transboundary issues, iv) provide spatially explicit uncertainty estimates.

To achieve this, both top-down and bottom-up mapping have been compared using the same mapping algorithm (quantile random forest) but with different input data: i) EU-level mapping, using the most predictive EU-level auxiliary variables (EU covariates and LUCAS point data) and applying a common EU inference model ii) country-driven mapping, using a) the best national covariates and point data (SIMS) b) the EU-level input data c) EU covariates and national point data and the other way around.

The spatial resolution chosen for the mapping exercise was a 100 m grid, which implied the production of an EU-wide covariate set at 100 m in INSPIRE-compatible projection by ISRIC. Soil properties commonly observed in both LUCAS and SIMS were selected for the maps, of which the methodologically most consistent pH was mapped first. Before the mapping exercise, comparative statistical parameters of the LUCAS and SIMS databases were examined. To develop appropriate methodological comparisons and transfer functions, analyses of both LUCAS and national methods on the same samples are ongoing.

Traditional and Digital Soil Mapping (DSM) use topographic characteristics to map soils. Soil maps provide inferences about soil water dynamics. However, in most cases the water dynamic characteristics used for soil classification are aggregated monthly and/or annually. Finer spatial and temporal characterization of soil water movement is needed to better understand soils and their functions which in turn would support management decisions at multiple scales from hillslope to watershed and regional. In this study we used a distributed soil vegetation hydrological model (DHSVM) to characterize soil water movement (soil moisture-SM and depth to saturation-WTD) at a hillslope scale under pasture. Modeled soil moisture was compared with sensor measured values at key slope positions (summit, sideslope and toeslope) and three depths. Temporal patterns of measured data matched those estimated by DHSVM. The positions of peaks and valleys between simulated and measured SM matched at depths 0-20 and 20-45 cm, as shown by the significant correlation coefficients that varied between 0.71 and 0.84. Simulated absolute values of SM were only accurate for the summit's surface and at depth 20-45 cm at the sideslope and toeslope, although correlations were strong and significant for all SM estimations at the first two depths. For other positions and depths, estimations were not accurate. The least accurate estimations were those for SM at depth 45-60 cm and WTD, which presented overall the weakest correlation coefficients. The validated soil moisture maps can be used to better characterize spatial-temporal soil dynamics for understanding soil development and precision agriculture applications.

Artificial neural networks (ANNs) have proven to be a useful tool for complex questions that involve large amounts of data, for example predicting soil classes on various scales. Our use case of predicting soil maps with ANNs is in high demand by government agencies, construction companies, or farmers, given cost and time intensive field work.

However, there are two main challenges when applying ANNs. In their most common form, deep learning algorithms do not provide interpretable predictive uncertainty. This means that properties of an ANN such as the certainty and plausibility of the predicted variables, rely on the interpretation by experts rather than being quantified by evaluation metrics validating the ANNs. This leads to the second challenge: these algorithms have shown a high confidence in their predictions in areas geographically distant from the training area or areas only sparsely covered by training data.

To tackle these challenges, we use the Bayesian deep learning approach “last-layer Laplace approximation”, which is specifically designed to quantify uncertainty into deep networks. It corrects the overconfident areas without reducing the accuracy of the predictions, giving us a more realistic uncertainty expression of the model's prediction. In our study area in southern Germany we divide the soils into typical soils of valleys, the Swabian Jura and the Black Forest. As a test case, we then explicitly exclude the soil types of Swabian Jura and Black Forest in the training area but include these regions in the prediction.

Our findings emphasize the need to address the issue of overconfidence in ANNs, particularly for distant regions from the training area. Moreover, the insights gained from this research are not only limited to addressing overconfidence in ANNs, but also offer valuable information on the predictability of soil types and identifying knowledge gaps. By analysing regions where the model has limited data support and, consequently, high uncertainty, stakeholders can recognize the areas that require more data collection efforts.

##### MODELLING THE DIVERSITY OF SOIL FUNCTIONS ACROSS EUROPE

A. WADOUX<sup>1</sup>, M. DEBELJAK<sup>2</sup>, P. LAGACHERIE<sup>3</sup>, R. CREAMER<sup>1</sup>

<sup>1</sup> LISAH, Université de Montpellier, INRAE, IRD, Institut Agro, Montpellier, FRANCE

Soils sustain a number of functions playing a key role in ecosystem functioning and providing a multitude of services to human society. While it is acknowledged that all soils are multifunctional, there is, to date, limited knowledge on how the supply of soil functions and their combination differ spatially with land use type, soil characteristics, climate and land use intensity at large geographical scales. We address this gap by quantifying five functions of major importance to European soils: 1) primary productivity, 2) water regulation, 3) climate regulation, 4) nutrient cycling and 5) provision of habitat for biodiversity. We built a multi-attribute semi-quantitative model with a hierarchical structure. The model is structured for the large-scale evaluation of soil functions and takes as input a set of indicators related to dynamic and stable soil properties, as well as to climate, topography and management practices, and returns qualitative aggregated attributes representing the soil functions fulfillment. Thresholds for the soil functions fulfillment are obtained by statistical analysis coupled with expert knowledge and vary across European environmental zones. The model is tested on a large European topsoil dataset in cropland and grassland. Statistical distributions of soil fulfillment are obtained as well alpha- and beta-multifunctionality representing the diversity of soil functions represented at a sampling location and the unique contribution of the sampled site to the regional (i.e. NUTS3 level) soil functions supply, respectively. We found that soil function fulfillment varied greatly across landscapes in Europe and between environmental zones. Spatial patterns of the alpha- and beta-multifunctionality revealed hotspot sites of multifunctionality (alpha diversity) but also sites providing a set of soil function fulfillment unique within the region (beta diversity). Few sites are both unique and highly diverse. Our study set a baseline estimate of soil functions in Europe as a prerequisite to consider soil functions in environmental planning.

**THE BENEFITS OF A MASSIVE HARVESTING OF LEGACY MEASURED PROFILES FOR MAPPING PRIMARY AND FUNCTIONAL SOIL PROPERTIES IN THE COASTAL PLAIN OF OCCITANIE (SOUTHERN FRANCE).**

P. LAGACHERIE <sup>1</sup>, L. COURTEILLE <sup>1</sup>, A. CHEMCHER <sup>2</sup>

<sup>1</sup> LISAH, Univ Montpellier, INRAE, IRD, Institut Agro, Montpellier, FRANCE

<sup>2</sup> Atos Montpellier, Pôle Data Driven Intelligence, Montpellier, FRANCE

The coastal plain of Occitanie is facing up to important issues related with the dramatic decrease of the water and soil resources caused respectively by the global climate change and the progresses of urbanization boosted by a large demographic growth. Mitigating such issues requires relevant decision making based on an accurate knowledge of the spatial distribution of soil properties over the region. For the last fifteen years, such a knowledge has been provided to end-users by the successive implementations of new digital soil mapping approaches: Developing GlobalSoilMap products (10.1016/j.geodrs.2014.11.003), Regional mapping of Soil Available Water Capacities (10.1016/j.geoderma.2021.114968) and of a Potential Soil multifunctionality index (10.1111/ejss.13345). However, the low spatial density of the sets of legacy measured profiles severely limited the accuracy of these mapping products, which in turn significantly hampered the consideration of soils in the land planners' decision making.

To face this problem, a massive harvesting of legacy soil profiles was conducted in the region, involving semi-automatic entry procedures based on automatic reading. This allowed to considerably increase the spatial density of legacy measured soil profiles that were used as input of DSM models (from 1 profile/ 9.9 km<sup>2</sup> to 1 profile/ 1.3 km<sup>2</sup>).

The new DSM models that were calibrated from this new soil dataset produced more accurate soil mapping products with lower predicted uncertainty. A subsequent effort was also conducted to communicate the remaining uncertainty under an adequate formalism (spatial aggregation, adapted semiology) that enabled a good appropriation of the soil maps by decision-makers.

The results obtained in this pilot region illustrated the feasibility of operational DSM approaches to support land planners' decision making at regional and territorial scales.

#### PEDODIVERSITY MAPPING IN AN ALPINE ENVIRONMENT

C. FERRÉ, G. MASCETTI, S. AGABA, M. MUSETTI, R. GENTILI, R. COMOLLI

University of Milano Bicocca, Milan, ITALY

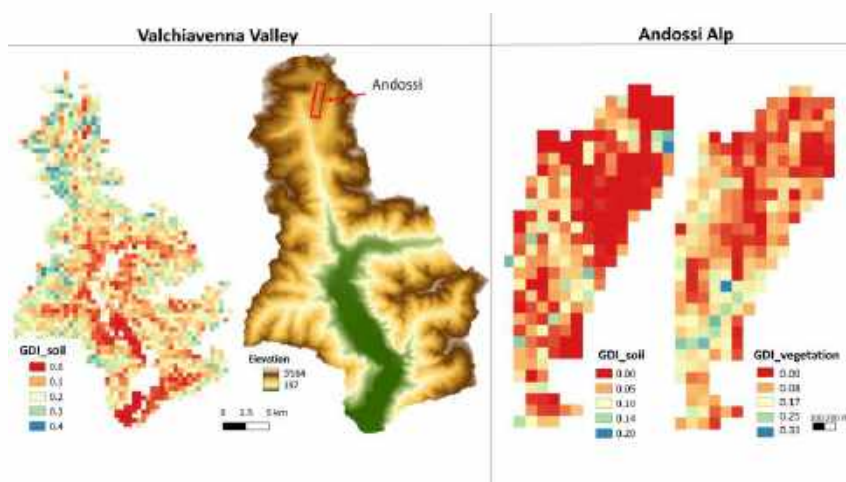

Diversity is the key to the ecosystem stability, as it provides resistance and resilience to environmental changes.

We mapped pedodiversity, defined both in terms of soil types and map fragmentation, operating at two scales: Valchiavenna valley (VCH; 450 km<sup>2</sup>), in the central Alps, and within it the Andossi Alp (AA; 3.5 km<sup>2</sup>). Pedodiversity was assessed in the following steps: 1) 232 and 126 soil profiles, for VCH and AA respectively, were classified (WRB, 2022); 2) geomorphometric variables (extracted from a 20 and 4 m resolution DTM for VCH and AA respectively) and vegetation indices (extracted from Sentinel 2 imagery) for AA only were used as covariates to model soil types; 3) Discriminant Analysis (for VCH) and Random Forest model (for AA) were used to produce soil maps (75% of data for train by cross-validation and 25% for test); 4) pedodiversity maps were obtained by calculating the Simpson's Diversity Index (SDI), the Relative Edge Density (RED) and the proposed Global Diversity Index (GDI, product of the former), on 25 ha (VCH) or 1 ha (AA) pixels; 5) pedodiversity was compared with diversity of land use and elevation for VCH, and with geomorphometry and vegetation diversity for AA.

The main soil types were Leptosols, Regosols, Cambisols, Umbrisols, Podzols, Fluvisols (only in VCH), Gleysols and Histosols.

The results showed that for VCH the GDI was on average  $0.16 \pm 0.09$  (maximum 0.43); the SDI was  $0.47 \pm 0.16$  (maximum 0.8) and the RED was  $0.30 \pm 0.10$  (maximum 0.55). The GDI was not related to land use but increased with elevation.

Regarding the AA pasture, the GDI was low ( $0.04 \pm 0.04$ ), due to a limited fragmentation (RED:  $0.09 \pm 0.07$ ); the typological diversity predominated (SDI:  $0.24 \pm 0.21$ ); soil diversity was positively related to geomorphometric diversity, but more strongly to vegetation diversity. In general, pedodiversity was greater in the southern part of the AA, where lithology and morphology were more diversified than in the northern part.

#### ISOLATING THE EFFECTS OF SOIL PHYSICAL PROPERTIES ON FRUIT COMPOSITION: A CASE STUDY IN MARYLAND, USA

J. FIOLA<sup>1</sup>, G. EVANYLO<sup>2</sup>, T. WOLF<sup>2</sup>, R. STEWART<sup>2</sup>

<sup>1</sup> Delaware Valley University, Doylestown, USA

<sup>2</sup> Virginia Tech, Blacksburg, USA

Soil is often credited with affecting various qualities in grapes and wine, but the specific effects of soil properties on grape chemistry lack an empirical basis. Most previous studies have either compared vineyards across geographic areas with climatic differences or taken soil out of its natural location and changed its properties. In this project, we attempted to isolate the influence of soil properties on grapevines and fruit composition by monitoring vines and fruit in an Alberino vineyard block in Maryland on the East Coast of the USA. Other variables were constant in the vineyard, including variety, climate, and vineyard management. We assessed within-block soil differences by completing soil descriptions and sampling across transects. The main soil difference we observed across site transects was topsoil depth (A-horizons), which ranged from 0-28 cm. We then monitored vine parameters including crop load, vine size, fruit exposure, cluster density, and primary fruit chemistry throughout the 2019, 2020, and 2021 growing seasons. To determine any effects of topsoil depth on vine parameters, we completed multiple linear regression analyses. The fruit showed variability in cluster density as well as chemistry, some of which was explained by differences in topsoil depth. The most consistent results were positive relationships between topsoil and fruit titratable acidity (TA), and between topsoil and cluster density. In 2019 and 2020, fruit titratable acidity was significantly lower in vines growing in thinner topsoil, indicating that the fruit was ripening earlier. In 2021, crop load was significantly correlated with TA, suggesting that out of balance vines superseded any potential soil effects. During all three years, there was a significant relationship between cluster density and topsoil depth, where vines in thinner topsoil had looser clusters (which is a positive attribute in the Eastern U.S.'s high disease pressure). The results increase our understanding of terroir, and the specifics of how topsoil affects vine size, fruit titratable acidity, and cluster density.

<sup>2</sup> Unesp - Campus Registro, Registro, BRAZIL

Information on the expected yield of vineyards is necessary for making decisions about the fertilization and nutritional management of grapevines. The study aimed to develop grape yield prediction models and evaluate the effect of inputting different data on model calibration. A database ( $n = 423$ ) derived from vineyards was used. The database comprises data from six harvests of Pinot Noir, Chardonnay, Merlot, Moscato and Isabel cultivars. Climate data (precipitation and average temperature) and soil type from the production field were retrieved. Nutrient contents in soil and leaves was used. The Random Forest machine learning method was used to calibrate prediction models considering five data input approaches: 1) soil+region, 2) climate, 3) soil+region+climate, 4) nutrient levels in soil and plant, and 5) all data. This resulted in five different models, which were evaluated by the coefficient of determination ( $R^2$ ), used as a measure of variance explained by the predictors and the Root Mean Squared Error (RMSE) and Maximum Absolute Error (MAE) used as a measure of dispersion in the predictions. To develop the models, the database ( $n = 423$ ) was randomly partitioned into calibration ( $n = 297$ ; 70%) and validation ( $n = 126$ ; 30%) data. Model 5 (all data) achieved the lowest average error rates in validation ( $R^2 = 0.89$ , RMSE = 4.18 t ha<sup>-1</sup>, MAE = 2.12 t ha<sup>-1</sup>), but very close to the performance of model 4 (nutrient levels) ( $R^2 = 0.85$ , RMSE = 4.60 t ha<sup>-1</sup>, MAE = 2.80 t ha<sup>-1</sup>), while the 1-2-3 models produced the worst results ( $R^2 = 0.65$ ; 0.59; 0.66, RMSE = 6.93; 7.52; 6.86 t ha<sup>-1</sup>, MAE = 4.51; 5.18; 4.46 t ha<sup>-1</sup>, respectively). The five most important predictor variables in the prediction were the Mg and N content in the leaf, soil type, producing region and precipitation. This study offers insights for future research on predictive modeling of grape yield.

#### INTER-ROW SOIL MANAGEMENT AFFECTING SOIL MOISTURE AND PLANT DEVELOPMENT IN A SLOPING VINEYARD

A. HOREL<sup>1</sup>, I. CSERESNYÉS<sup>1</sup>, T. ZSIGMOND<sup>1,2,3</sup>

<sup>1</sup> Department of Soil Physics and Water Management, Institute for Soil Sciences, HUN-REN Centre for Agricultural Research, Budapest, HUNGARY

<sup>2</sup> National Laboratory for Water Science and Water Security, Institute for Soil Sciences, HUN-REN Centre for Agricultural R, Budapest, HUNGARY

<sup>3</sup> Doctoral School of Environmental Sciences, Loránd Eötvös University, Budapest, HUNGARY

This three-year study aimed to explore the effects of inter-row soil cover and management on soil water content (SWC) and plant health in a sloping vineyard. We used two vineyard treatments: GR, which had a permanent grass cover between the rows, and CC, which had tillage in the first year, cover crops sowed in the second year, and a perennial cover crop grown in the third year. We used sensor sets to measure SWC, soil temperature, and vineyard plant growth indicators such as Normalized Difference Vegetation Index (NDVI), Photochemical Reflectance Index (PRI), and fraction of Absorbed Photosynthetically Active Radiation (fAPAR) at different slope locations.

Our study revealed clear variations between the studied inter-row managed sites and within slope positions. CC site had significantly ( $p < 0.05$ ) higher overall SWC at 15 and 40 cm depths compared to the GR site. Slope positions showed a significant influence on NDVI and PRI ( $p < 0.001$ ), but not on fAPAR. The LAI at the CC grapevine was higher by 18% compared to GR, however, it was not significant ( $p = 0.16$ ). Plant parameters showed moderate relationships with specific soil parameters, such as soil organic carbon, total N, pH, or SWC. Continuous cover crop inter-row management significantly reduced the SWC for the upper soil layers (i.e. third year), however, for plant development (fAPAR) it can be beneficial. Based on the PRI values, our results indicated better light use during photosynthesis and better grapevine productivity for the GR site compared to the CC, especially during the first year (i.e. tillage). Overall, we found that the soil and plant characteristics in vineyards were strongly affected by the type of inter-row soil management with cover-crop inter-row might be a good option when drought conditions are rare.

Acknowledgments: This material is based upon work supported by the Hungarian National Research Fund (OTKA/NKFI) project OTKA FK-131792.

#### CARBON SEQUESTRATION POTENTIAL IN ENGLISH VINEYARDS

H K G YAHAMPATH ARACHCHIGE, [M PARADELO](#)

Natural Resources Institute - University of Greenwich, Chatham Maritime, Kent, UNITED KINGDOM

Agroecosystems are crucial for maintaining global carbon balance due to their capacity for carbon sequestration (CS). Amongst the cultivated lands through which the CS can be increased, vineyards are identified as high-potential sites. For instance, the physiological features and function of grapevines, cover crops, and associated soil management practices can increase vineyards' soil organic carbon (SOC) levels. With global warming, vineyards' hectareage is expanding in colder countries located above 50° N. In England, vineyard areas expanded by 3,100 ha between 2004 and 2021. However, the impact of this expansion on the CS of soil and the existing carbon stores has not yet been explored.

This study aimed to assess the CS potential of vineyards by analysing the soil organic carbon (SOC) content in 48 grapevine plots across England, in terms of age, depth and physiochemical soil properties. Secondary data was obtained from the LUCAS database. The results showed that the top 10 cm contained more SOC than the 20 cm for all soils. However, the change of SOC percentage with age varied in different vineyards: the majority of the vineyards investigated showed a positive increase in SOC percentage in both 10 and 20 cm. Most importantly, the clay content of soil played a key role in SOC accumulation ( $R = 0.606$ ) compared to the other physiochemical properties. The SOC in the studied plots was compared to grasslands and croplands in the same pedoclimatic zone from the LUCAS database. The mean SOC percentage of vineyards ( $2.41 \pm 1.05\%$ ) was lower than the grasslands' ( $3.67 \pm 2.08\%$ ) but higher than the croplands' ( $2.03 \pm 0.86\%$ ). Hence, it could be suggested that the grapevine and grass combination in vineyards may increase the SOC level in the soil.

<sup>4</sup> University of Naples Federico II, Portici (NA), ITALY

The viticultural sector is one of the most challenged agricultural sectors by Climate change (CC), needing specific adaptation and mitigation actions to make local farming communities resilient and preserve the expression of terroir.

The latter is dependent on soil-plant-atmosphere (SPA) system interactions and in particular on the vine water status, affecting berries characteristics such as sugar, anthocyanins, flavonoid concentration, and acidity.

Under climate change, irrigation represents a complex issue. In fact, it is not only important to guarantee water to the plants, but to maintain a specific water stress during the ripening phase of the grapes.

The aim of this contribution is to show the first results of a task of Spoke 3 of the National Research Center for 'Agriculture Technologies - Agritech' (NextGenerationEU European program) on the identification of procedures for the optimized management of the water resource in vineyards.

We used a multidisciplinary approach to support irrigation optimization in vineyard. It is based on two main steps: 1) the identification of the functional homogeneous zones (fHZs) in the vineyard through an environmental analysis based on the soil spatial variability, the micro-morphology of the vineyard (LIDAR) and the spatial variability of the crop response at different resolutions (UAV); 2) monitoring plant and soil water status in the fHZs to optimize the irrigation achieving the field oenological goals while preserving the water resource.

We ran a test on an Aglianico vineyard (2 ha) of Tenuta Donna Elvira winery (Montemiletto, AV). Two weather stations and seven monitoring nodes were distributed within the irrigated and non-irrigated long plots.

The irrigation supply was realized through an automated irrigation system (MySOLEM) and defined according to the leaf water potential (LWP) measured, keeping its value between 1.2 and 1.4 bar during the ripening period.

At the end of the first year, we analyze collected data to develop a vineyard water management model able to support achieving oenological goals and facing climate change.

The increasing warming and drought caused by climate change in the Mediterranean area affects grapevine yield and berry quality, particularly in some of the autochthonous grape varieties in the Campania Region of southern Italy. The productivity and quality of vineyards depend on pedo-climatic conditions, and adopting appropriate cultivation techniques such as soil and canopy management can help mitigate the effects of climate change, maintaining or improving grape yield and berry quality.

The aim of this study was to evaluate the combined effect of two types of canopy management (double guyot and double guyot flipped) and three treatments of soil management (cover crops, natural coverage, and soil tillage) on the Greco grapevine responses to study the relations of soil-plant-atmosphere system (SPA) and support the identification of specific adaptation and mitigation actions to climate change for this cultivar. The study was conducted over three years (2020-2022) in a Greco experimental vineyard of Feudi di San Gregorio winery in southern Italy (Avellino), on a Calcaric Cambisol within the Rural Development Programme 2014-2020 of Campania Region.

The status of vines was monitored using a multidisciplinary approach that allowed the analysis of vine behavior at the single plant to vineyard levels. Biometrical parameters, leaf water potentials, and functional anatomical parameters linked to the efficiency of gas-exchanges and water flow were measured to monitor growth and eco-physiological traits of vines. Yield components and berry characteristics were determined at harvest, meteorological data and soil water content monitored.

Finally, in each experimental plot SWAP model was calibrated and validated to understand the relation between plant water stress and grape characteristics. The validated model was successfully applied to simulate climate change's effect (RCP 8.5 scenario) on the SPA system studied.

The multidisciplinary approach proved to be fundamental in going in-depth into the cause-effect relations and mechanisms for vines acclimation, finding a sustainable solution to face climate change in the vineyards of southern Italy.

#### THE EFFECTS OF SOIL AERATION IN COMBINATION WITH A BIO-STIMULANT IN A VINEYARD IN THE TOKAJ WINE REGION

P. BALLING<sup>1</sup>, I. KISS<sup>1</sup>, A. KNEIP<sup>1,2</sup>, P. MOLNÁR<sup>1</sup>, L. VARGA<sup>1,2</sup>

<sup>1</sup> UNIVERSITY OF TOKAJ-HEGYALJA, LÓRÁNTFFY INSTITUTE, DEPARTMENT OF VITICULTURE AND OENOLOGY, SÁROSPATAK, HUNGARY

<sup>2</sup> RESEARCH INSTITUTE FOR VITICULTURE AND OENOLOGY, TOKAJ, TARCAL, HUNGARY

Many challenges have arisen in vineyard soil management, such as soil compaction, soil cover, and disease control. One of the most important diseases that can be transmitted through the soil is grapevine trunk disease (GTD), which is caused by fungi. GTD is a complex disease and the infection (symptoms) can be latent. Numerous studies have focused on *Trichoderma* spp. biostimulants, hyperparasitic fungal material as disease control agents against GTD.

In this study, the *Trichoderma* spp. application method was combined with soil aeration (KX016-4 mini excavator with compressor and 60-litre tank with a hydraulic hammer). The vineyard is located in Tokaj and was planted on Cambisol loess soil, using a combination of Furmint T85 scions and Teleki 5C rootstocks. Six parcels were involved in the experiment by two parallel rows (50-50 vine). Treatments were carried out by aeration with *Trichoderma* spp. suspension (TR04, TR05 strains 10 million cells/mL) and by irrigation directly in the soil. A total of 300 vines (aeration, irrigation, and control blocks) were observed between 2020 and 2022, and records of external GTD symptoms were carried out yearly. The incidence of *Trichoderma* spp. strains were determined each year on randomly selected vines. GTD disease monitoring has been completed with leaf area index (LAI) calculation with VitiCanopy® software and cane weight measurement has been used for biomass analysis.

The results showed that the use of the biostimulant is effective as a biocontrol agent against GTD. Fungal strains (TR04, TR05) were isolated from all samples of treated vines irrespective of the application method. They were colonized through the soil by *Trichoderma* spp. The visual appearance of GTD decreased during the study period as a result of the treatment. An increase in the LAI was also observed for each of the methods. However, the soil aeration proved effective in increasing cane weight. There is a need for further studies to improve the method and to assess the effectiveness of the treatment.

#### ASSESSING THE IMPACT OF LANDSCAPE, CLIMATIC VARIABLES AND SOIL MANAGEMENT ON ORGANIC CARBON CONTENT IN VINEYARD SOILS

A. EDUARDO <sup>1</sup>, E. GONZALEZ <sup>2</sup>, R. ROA-ROCO <sup>3</sup>, M. MIRANDA <sup>1</sup>

<sup>1</sup> Pontificia Universidad Catolica de Chile, Santiago, CHILE

<sup>2</sup> Center of Applied Ecology and Sustainability, Santiago, CHILE

<sup>3</sup> Centro de Investigación e Innovación Viña Concha y Toro, Talca, CHILE

Vi industry is one of the most important in agriculture in Chile, covering a total area close to 130,000 hectares, located mainly in the central region. Understanding the drivers and developing efficient modeling techniques to assess potential increases in Soil Organic Carbon (SOC) storage is vital to mitigate management impacts. This understanding, coupled with accurate calibration of vineyard management process models, can help assess their role in soil carbon dynamics.

This study aims to model variables explaining soil organic carbon content based on farm, management and landscape variables. A total of 205 points were sampled across six vineyards at depths of 15 and 30 cm. These variables include soil properties (pH, texture, electrical conductivity), climate (average temperatures and rainfall), relief (height, exposure, slope), vegetation, lithology of the parent material, and agricultural management practices (manure application, tillage intensity). The latter category considered variables such as planting age, type and frequency of plowing, irrigation, presence of spontaneous vegetation between planting rows, and fertilization.

A combination of modeling techniques including Machine learning methods, specifically a random forest-based variable dimensionality reduction algorithm and generalized linear models (GLM), were employed to analyze the effect of edaphic and topoclimatic variables on the organic carbon content of soils in vineyards under conventional and organic management in Central Chile. Preliminary results indicate that GLM can explain up to 52% of the variability of the organic carbon content of the studied soils. Precipitation and altitude emerged as the most influential predictive variables, with soil texture and salinity being the most important soil management practices. In conclusion, our findings suggest that landscape and climatic data have a greater influence in explaining organic carbon content compared to management variables, highlighting the importance of these factors in viticulture carbon dynamics

#### 6.05 131572 - Advancing Quantitative Soil Classification: From Soil Profiles to a Dynamic and Comprehensive Classification System

##### A GLOBAL NUMERICAL CLASSIFICATION OF THE SOIL SURFACE LAYER

A WADOUX <sup>1</sup>, A MCBRATNEY <sup>2</sup>

<sup>1</sup> LISAH, Univ. Montpellier, IRD, INRAE, Institut Agro, Montpellier, FRANCE

<sup>2</sup> Sydney Institute of Agriculture & School of Life and Environmental Sciences, The University of Sydney, Sydney, AUSTRALIA

The quest for a global soil classification system has been a long-standing challenge in soil science. There currently exists two, seemingly disjoint, global soil classification systems, the USDA Soil Taxonomy and the World Reference Base for Soil Resources, and many regional and national systems. While both systems are acknowledged as international, there remain various examples of their shortcoming for accounting of topsoil features, local applications and communication with established regional classification systems. This calls for a numerical soil classification that addresses these discrepancies and achieves harmonization with existing national systems. In this paper, we report on the development of a layer classification system -as opposed to the classification of soil profile entities, as a first step towards achieving a comprehensive global numerical soil classification not based on a priori defined classes. We implemented a modelling approach with a set of predicted key soil properties available globally for the soil surface layer with the same depth range of 0-5 cm. The set of properties were partitioned into a number of homogeneous and disjoint classes using the k-means clustering algorithm. Next, we investigated the pattern of variation of the clusters in association with the soil property map with principal component analysis. A three-component nomenclature system is derived in a transformed space of the class-specific centroids to account for the uneven distribution of the centroids in the principal component space. We show that it is possible to build a data-based objective numerical taxonomic classification of soil layers, and that existing sets of key soil properties, predicted separately, coalesce into identifiable clusters or classes and manifest discernible spatial and/or pedological patterns. This grouping of key soil properties to logical categories is a possible step to better define diagnostic horizon features and suggest new ones. The general-purpose map of soil surface layer classes of the world also has potential applications in assessing soil change and designing monitoring surveys.

<sup>3</sup> University of -Miskolc, Miskolc, HUNGARY

Recent advancements in national and global soil classification systems have primarily relied on expert knowledge, neglecting the vast potential offered by digital soil information archives at both national and global levels for statistical analysis. The validation of soil classes, diagnostic units of classification systems, using legacy soil information and statistical methods remains largely underexplored. In our ongoing efforts to optimize and validate the Hungarian Diagnostic Soil Classification System (HDSCS), we have employed an iterative approach involving algorithmization, numerical, and statistical methods. These methodologies contribute to the substantiation of classification units, allowing for the optimization of criteria, thresholds, and the order of the classification key. The outcomes of this process have led to an enhanced version of the classification system, providing a more accurate characterization of the country's soil conditions and improving the overall user experience. This presentation showcases the supporting legacy database, algorithmization results, and numerical and statistical characterizations, highlighting the evolutionary steps that culminate in the final optimized version.

##### CONSERVATION AGRICULTURE INCREASES TOPSOIL ORGANIC CARBON STOCKS IN BRAZIL – A MULTI-MODELING APPROACH

E. BRUNI<sup>1</sup>, M. GERVASIO PEREIRA<sup>2</sup>, J. ROSSET<sup>3</sup>, J. TORRES<sup>4</sup>

<sup>1</sup> Ecole Normale Supérieure - Laboratoire de Géologie, Paris, FRANCE

<sup>2</sup> Universidade Federal Rural do Rio de Janeiro, Seropédica, Rio de Janeiro, BRAZIL

<sup>3</sup> Universidade Estadual de Mato Grosso do Sul, Mundo Novo, Mato Grosso do Sul, BRAZIL

<sup>4</sup> Instituto Federal do Triângulo Mineiro, Uberaba, Minas Gerais, BRAZIL

In Brazil, conservation agriculture (CA), which includes no-tillage along with crop residue maintenance, cover cropping and/ or mixed crop rotations has been widely adopted to reduce soil erosion, with consolidated benefits for sustainability and land degradation control. The potential of CA to increase soil organic carbon (SOC) stocks in Brazil has not been studied yet in the context of the “4 per 1000” initiative, which proposes an aspirational 4‰ annual target for SOC stock increase.

The objective of this study was to estimate the capability of CA systems in tropical and sub-tropical sites to increase SOC stocks, relative to tilled systems without cover cropping.

For that, we collected data from three agricultural experiments in Brazil with different edaphoclimatical conditions, where several principles of CA were implemented. Then, we studied the effect of CA on topsoil OC stocks and compared it to different land management scenarios. That is, a scenario with conventional tillage, one without cover crops, and one with conventional tillage and no cover crops. We developed several methods to take into account the effects of tillage on SOC decomposition. We implemented them in an ensemble of SOC models (e.g., Century, ICBM, and Roth-C) and calibrated the models with a Bayesian approach, in order to account for both parameter and structural uncertainties.

Considering different possible representations of SOC processes allowed us to reliably assess the impact of conventional tillage on topsoil OC stocks and to uncover the structural lacks of the models. Preliminary results show that the land management with the highest SOC stock increase was CA, independently of the type of cover crop used. We found that under conventional tillage and no cover cropping, an annual 4‰ increase of SOC stocks at the studied site is unlikely, whereas the other scenarios generally showed an annual increase higher than 4‰.

##### CROP MODELLING TO SUPPORT SPATIAL N MANAGEMENT IN UK WHEAT

D. CLARKE<sup>1</sup>, S. HALLETT<sup>2</sup>, J. HANNAM<sup>2</sup>, B. MARCHANT<sup>2</sup>, E. STOCKDALE<sup>1</sup>

<sup>1</sup> NIAB, Cambridge, UNITED KINGDOM

<sup>2</sup> Cranfield University, Cranfield, UNITED KINGDOM

<sup>3</sup> British Geological Survey, Keyworth, UNITED KINGDOM

Heterogeneous soil properties within fields can vary as much as they do across regions, causing spatial and temporal variation in crop growth and nutrient demand. For wheat economic optimal nitrogen (N) has been demonstrated to vary by  $>150$  kg N ha<sup>-1</sup> with N fertilizer recovery ranging between 30%-100% within fields. Spatially accurate N fertiliser application can, therefore, improve nutrient use efficiency as a whole field/system and forms the foundation of precision agriculture. Current spatial management technologies focus on economic return, with little consideration to environmental consequences. The challenge is balancing these often conflicting, demands. Crop models describe changes in systems in response to weather or management, quantifying how these impact interacting components including crop, soil, and system losses. Crop simulation models could identify spatially specific management strategies considering both economic and environmental impacts. To develop the technology in the context of UK wheat; firstly, a systematic review of the literature using crop simulation modeling for PA globally was performed identifying key themes for methodology development. Secondly, using the high spatial-temporal data resolution from a long term experiment the Sirius crop model was calibrated and validated across observed spatial-temporal variation in soil properties and crop growth. Thirdly, a methodology for whole farm yield map geo-spatial analysis was developed to reduce the spatial data demands for crop model parametrisation on farm. Targeted sampling based on homogenous management zones was used to spatially parametrise, validate, and apply crop simulation models to manage spatial variation across the homogenous yield zones identified. This research has demonstrated the applicability of crop simulation modeling for making spatially relevant on farm N management decisions. Future work aims to develop rotational modeling approaches and further experimental modeling to explore how models can be used to make more informed soil management decisions.

##### NOVEL APPROACHES TO REPRESENT REGENERATIVE AGRICULTURE MANAGEMENT IN THE MEMS MODEL

Y. ZHANG, R. SILVA SANTOS, A. KING, E. HAMILTON, H. YANG, P. STANLEY, S. OGLE, K. PAUSTIAN, M.F. COTRUFO

Colorado State University, Fort Collins, USA

Soil carbon sequestration stands as a critical strategy for mitigating climate change by reducing atmospheric CO<sub>2</sub> levels. Regenerative agriculture has emerged as a promising way for enhancing carbon sequestration in soil. While traditional soil carbon models have been utilized to estimate sequestration potential, the latest generation of models use measurable soil carbon pools and incorporate an updated understanding of decomposition processes, but they are yet to be widely adopted to simulate the impact of regenerative agriculture. The MEMS ecosystem model, initially designed for grassland systems, has recently been developed to simulate annual crop and forage growth, as well as cropland and grazing land regenerative management practices. Through calibration and validation across diverse systems and environments, this model's results will be presented and discussed. The novel approaches built in the model enhance our comprehension of carbon sequestration in regenerative agriculture, offering valuable insights to develop effective strategies in the fight against climate change.

<sup>3</sup> Karotin Ltd, Szeged, HUNGARY

Over 60% of European soils exhibit signs of degradation, and compelling scientific evidence indicates that this phenomenon persists due to unsustainable land management practices, soil sealing, contamination, and overexploitation. The repercussions of degraded soils extend significantly, adversely impacting essential ecosystem services such as food production, carbon sequestration, and water regulation, among others. Despite the annual challenges faced by many farmers due to climate change and soil degradation, the adoption of conservation or regenerative agriculture remains surprisingly low. This can be attributed to various factors, lack of trust in new agricultural technologies stemming from limited accessible information and scientific evidence.

The lack of experimental studies that suit local conditions contribute to a steep learning curve in the adoption of regenerative agriculture technologies in different geographical regions. Despite large number of global studies on regenerative in various combinations over the past decades, their widespread adoption faces obstacles. In our research, we sought to amalgamate pertinent archival information from scientific literature with on-farm research findings. Additionally, for benchmarking purposes, we incorporated a national soil monitoring database containing soil physical, chemical, and biological information.

Our objective was to develop a machine learning-based Decision Support System (DSS) that facilitates the intensification of conservation and regenerative technologies among farmers. The DSS relies on a farm-specific database encompassing soil properties, landscape characteristics, climate, crop rotation, mechanization, input usage, and yield information. This data enables the identification of key weaknesses in agricultural practices. Subsequently, the DSS matches relevant technologies from analogous environmental conditions and models their effects on key environmental indicators and farm profitability. The DSS then ranks these pathways based on low-cost, and high-impact considerations.

<sup>2</sup> UKCEH, Wallingford, UNITED KINGDOM

The ASSIST/Agzero modelling framework is an integration of two terrestrial process-based models (The Rothamsted Landscape model and NCP14) and a hydrological model (LTLS-freshwater model or LTLS-FM). The Rothamsted Landscape Model simulates processes in agricultural soil, including dynamics of organic matter, nutrients and water. It also simulates livestock production, crop growth and yield, including interactions with arable weeds. The UKCEH N14CP model simulates soil and vegetation processes in semi-natural areas. The new coupled model framework has been used to predict soil-nutrient delivery to rivers across Great Britain at a 5km x 5km scale. Here we describe the development of an erosion module that is integrated into RLM. We apply various near-future scenarios for land use and management change and use the modelling framework to predict the impacts on outcomes including soil-nutrient loss to water.

##### SOIL GHG MITIGATION POTENTIAL AND ECOSYSTEM MODEL UNCERTAINTY QUANTIFICATION

S. DEL GROSSO <sup>1</sup>, S. OGLE <sup>2</sup>, R. GURUNG <sup>2</sup>

<sup>1</sup> USDA ARS SMSBRU, Fort Collins, USA

<sup>2</sup> Colorado State University NREL, Fort Collins, USA

The DayCent plant-soil system model is used to calculate GHG emissions from most cropped and grazed soils in the USA reported in the National GHG Inventory and submitted to the UNFCCC. The model can also be applied to estimate the impacts of different management practices on soil N losses and C changes. We present results comparing the N and C consequences of management interventions such as use of enhanced efficiency fertilizers, reduction in tillage intensity, and growing cover crops. It is important to rigorously quantify uncertainty in both baseline emissions and mitigation potentials. Simplifications imbedded in model structure, imprecise values for model parameters, and uncertainty in input data contribute to overall model prediction uncertainty. We compared two methods for quantifying uncertainty, a Bayesian approach and an empirical-based method. Both are integrated into the DayCent architecture developed for the national GHG inventory. We calibrated DayCent with a Bayesian model analysis framework using different long-term cropland and grassland experimental sites, and then simulated C stock changes with random-draws from the posterior distributions. With the empirical-based method, we simulated experimental sites with DayCent and then developed a statistical model to estimate the accuracy of the predictions. We compared the estimates and uncertainties from both methods for predicting soil C changes from a region in the US corn belt. We also partitioned the total uncertainty among various sources to inform management of uncertainty.

#### EFFECTS OF EPHEMERAL GULLIES ON TILLAGE TRANSLOCATION AND TOTAL SOIL EROSION— MEASUREMENT, MODELING AND VALIDATION

S LI <sup>1</sup>, F ZHENG <sup>1</sup>, D LOBB <sup>2</sup>, D VIEIRA <sup>3</sup>, Y JIANG <sup>4</sup>

<sup>1</sup> Agriculture and Agri-Food Canada, Fredericton, CANADA

<sup>2</sup> University of Manitoba, Winnipeg, CANADA

<sup>3</sup> United States Department of Agriculture, Oxford, USA

<sup>4</sup> Agriculture and Agri-Food Canada, Charlottetown, CANADA

Ephemeral gullies are channel features created by water erosion on sloping landscapes. They are often flattened by tillage operations to prevent them from developing into classic gullies. Locations of the ephemeral gullies are mostly determined by topography thus they reoccur at the same locations year after year. This repeated cycle of creation and filling of ephemeral gullies can significantly affect the overall soil erosion in the field. In this study, we carried out a plot experiment to measure the effects of existing channels (ephemeral gullies) on tillage translocation. Tillage translocation were measured under three tillage treatments: downslope (DT), upslope (UT), and contour tillage (CT) with three channel treatments: no channel (C0), 10 cm by 10 cm channel (C10), and 20 cm by 20 cm channel (C20). The results indicate that for DT, the presence of a channel reduced total translocation, whereas for UT, it increased total translocation. For CT, the presence of a channel increased both forward and lateral soil translocation, and therefore total translocation. The results were used to develop a modified version of the Directional Tillage Erosion (ModDirTilLEM) to simulate tillage erosion. This model was combined with the Raster-RUSLE2 (RUSLER) for sheet/rill erosion and the Ephemeral Gully Erosion Estimator (EphGEE) for gully erosion to simulate both tillage and water erosion in two sites in Atlantic Canada. The model estimated erosion rates were validated against field measurements using the Cs-137 technique. It was found that the models provided reasonable estimations for individual erosion processes. The integrated model was able to provide accurate estimations of total soil erosion for most parts of the fields. However, around the ephemeral gully areas, errors and uncertainties were high. This highlights the dynamic nature of soil redistribution in the ephemeral gully areas, which calls for higher density in both temporal and spatial scales for soil sampling or modeling in these areas for soil erosion assessment.

**Keywords:** Channel, Interactive erosion processes, Cs-137

#### CHARACTERISTICS OF SOIL ERODIBILITY IN HUBEI PROVINCE OF CHINA

L. LIN<sup>1</sup>, Y. HE<sup>1</sup>, S. DING<sup>1</sup>, H. JIANG<sup>1</sup>, X. ZENG<sup>1</sup>, C. YI<sup>1</sup>, W. YANG<sup>2,3</sup>

<sup>1</sup> College of Resources and Environment, Huazhong Agricultural University, Wuhan, CHINA

<sup>2</sup> Hubei Water Resources Research Institute, Wuhan, CHINA

<sup>3</sup> Engineering technology research center of soil and water conservation in Hubei Province, Wuhan, CHINA

Large-scale evaluation of the soil erodibility factor ( $K$ ) for the topsoil layer plays a crucial role in formulating soil and water conservation strategies. A notable challenge in Hubei province of China has been the dearth of spatial soil data necessary for calculating the  $K$ -value across various soil and water conservation zones. The objective of this study was to investigate the distinctive characteristics of  $K$  values across the eight diverse soil and water conservation zones in Hubei Province. To achieve this, we collected 556 soil datasets encompassing metrics such as soil particle composition, soil organic carbon (SOC), land use, and parent materials through the National Soil Survey. These datasets covered different zones (DJK, NY, DB, MF, TB, JH, DT, and EY) and were employed in computing the  $K$ -values using the EPIC model. The results showed that soil erodibility  $K$  value ranged from 0.0157 to 0.0545  $t \cdot hm^2 \cdot h (hm^2 \cdot MJ \cdot mm)^{-1}$  with a mean value of 0.0382 in Hebei. Notably,  $K$  exhibited its highest value in the DT zone and its lowest in the TB zone. The spatial variability of the  $K$  value across the eight zones was related with the land uses and the underlying parent materials. The  $K$  values followed an order of badland (0.0403  $t \cdot hm^2 \cdot h (hm^2 \cdot MJ \cdot mm)^{-1}$ ) > upland > paddy field > forest > mud flat > shrubland > garden > grassland (0.0353  $t \cdot hm^2 \cdot h (hm^2 \cdot MJ \cdot mm)^{-1}$ ), with this pattern being attributed to the influence of SOC. The red soils derived from quaternary sediments, calcareous soils originating from carbonate rocks, and purple soils derived from purple sandstones and shales exhibited the highest  $K$  values on average, followed by the soils originating from fluvial & lacustrine deposits, quartz rocks, mudstones, red sandstones and shales, basic crystalline rocks, acidic crystalline rocks, and neutral crystalline rocks. The results can provide reference for predicting soil erosion and facilitating the development of zone-specific soil management plans within the soil and water conservation zones in Hubei province in the future.

This study reviews the researches of soil erosion mapping over the past 90 years, summarizes the achievements, identifies knowledge gaps that need further investigation, to provide theoretical references for global soil erosion mapping efforts.

'Reconnaissance Erosion Survey of the United States' of 1:5,000,000 published in 1935, which marking the beginning of large-scale regional soil erosion mapping. In the 1940s to 1960s, China and the former Soviet Union conducted national soil erosion mapping. In the late 1980s, remote sensing and GIS technology were applied to soil erosion survey and mapping. With the accumulation of scientific data and the improvement of computing capabilities, large-scale soil erosion mapping entered the fully digital mapping stage in the 21th century.

The scientific achievements of soil erosion mapping so far can be summarized as follows. A large amount of data has been generated and accumulated, a scientific and visual ontology for large regional (national to global) soil erosion research has been created, historical background and baseline for the study of dynamic soil erosion at large regional scales have been provided, the classic paradigm of regional soil erosion mapping has been developed.

However, researchers of regional soil erosion mapping has to face several challenges that need to be overcome.

Researches on regional soil erosion mapping should be conducted in the following areas: develop innovative paradigms for digital soil erosion mapping, improve the theory of regional soil erosion influencing factors and algorithms for generating data products of soil erosion factors, legacy data rescue, systematic analysis and application of soil erosion maps.

#### CALCULATION AND ANALYSIS OF SOIL ERODIBILITY FACTOR (K) ON A GLOBAL SCALE

M. YANG <sup>1</sup>, Q. YANG <sup>1</sup>, K. ZHANG <sup>2</sup>, R. LI <sup>3</sup>, G. PANG <sup>1</sup>, C. WANG <sup>1</sup>, L. WANG <sup>1</sup>, Y. LONG <sup>1</sup>

<sup>2</sup> College of Geography, Beijing Normal University, Beijing, CHINA

<sup>3</sup> Institute of Soil and Water Conservation, Chinese Academy of Science and Ministry of Water Resources, Yangling, CHINA

The soil erodibility factor (K) is the main parameters for large-scale soil erosion mapping using USLE/CSLE, is usually estimated uses soil physicochemical attributes and models, such as USLE-K, RUSLE2-K, EPIC-K, Dg-K. However, it remains to be studied which algorithm is more suitable to calculate K in the global scale. While, K is mostly calculated based on soil physicochemical attributes, which does not including the content of rock fragments which actually impact the K. In this study, USLE-K, RUSLE2-K, EPIC-K and Dg-K and SoilGrids v2 were used to estimate the global K and generate a K maps with 1km resolution, and analyze the spatial pattern and main controlling factors of the estimation results. The 106 point measured data of K were collected, and a database was established. The applicability of the calculation results of the above four algorithms was analyzed, and the estimated values of the four algorithms were modified. Then the USLE-K algorithm was taken as an example to calculate the effect of rock fragments in the soil profile and rock fragments on the soil surface. The results showed that (1) The spatial pattern of global K factors estimated by the USLE-K, RUSLE2-K, EPIC-K and Dg-K models is similar, with some extent different in statistical distribution. (2) The mean value of the result estimated by RUSLE2-K is the closest to the measured K factor, followed by the USLE-K algorithm and the EPIC-K algorithm, while the estimated K by Dg-K algorithm is quite different from the measured K factor. (3) The presence of rock fragment in the soil profile increases the global K by 2.84%. The rock fragment on the soil surface reduces K by 6.98%. The most affected soil types are Arenosols, Cambisols, Leptosols, etc. This study is of great significance for the global soil erosion mapping. An earlier version of this research data was made available to the FAO Global Soil Erosion Mapping Group in 2019.

#### A MULTISCALE STUDY ON THE SPATIAL DISTRIBUTION AND DEVELOPMENT PATTERNS OF EPHEMERAL AND PERMANENT GULLIES

C. WANG, Q. YANG, G. PANG, Y. LONG, L. WANG, J. WEI, S. LI, H. LIU, L. MA

College of Urban and Environmental Sciences, Northwest University, Xi'an, CHINA

Gullies have become significant issues in the Mollisol region of Northeast China, threatening national food security. Ephemeral and permanent gullies are the primary types of gullies. Many permanent gullies originate from ephemeral gullies, and once ephemeral gullies transform into permanent gullies, it signifies the destruction of soil resources, making remediation extremely challenging. This study extensively utilized high-resolution remote sensing and GIS spatial analysis at the regional, watershed, and hillslope scales to investigate gullies spatial distribution and development patterns in the Songnen Mollisol region of China (214,000 km<sup>2</sup>). The main findings are as follows:

(1) A stratified systematic sampling approach was employed at the regional scale to establish about 1000 small watershed units. Ephemeral gullies and permanent gullies were investigated based on sub-meter resolution imagery. Furthermore, field surveys of gullies and centimeter-level unmanned aerial vehicle (UAV) remote sensing surveys were conducted in 50 randomly selected small watersheds. By considering influential factors such as climate, soil, topography, and management practices associated with gully development, the spatial distribution patterns of ephemeral and permanent gullies in the Songnen Mollisol region were elucidated.

(2) At the watershed scale, we studied the dynamic development of gullies over the past decade. This research clarified the development rates, distribution patterns, and topographic threshold of ephemeral gullies transitioning into permanent gullies within ten years. This quantification of the impact of ephemeral gully development on the black soil region of Northeast China provides essential insights.

(3) At the hillslope scale, based on GNSS RTK measurements of morphological parameters of gullies during multiple runoff events in nine typical slopes over a two-year period. Developmental patterns of ephemeral and permanent gullies along hillslopes from top to bottom were analyzed. The key areas where ephemeral gullies transition into permanent gullies at the slope scale were accurately simulated.

This study can serve the national gully control efforts and provide scientific evidence and technical support for preventing and controlling black soil degradation.

#### VALIDATIONS OF RAINFALL EROSIIVITY ESTIMATED WITH HIGH SPATIOTEMPORAL RESOLUTION GRID PRECIPITATION DATASETS IN CHINA

Y. XIE <sup>1,2</sup>, B. YIN <sup>3</sup>, B.Y. LIU <sup>2,3</sup>, S.Q. YIN <sup>1</sup>, T.Y. YUE <sup>4</sup>

<sup>4</sup> Shanghai Regional Climate Center, Shanghai, CHINA

Rainfall erosivity is the key driving force of water erosion, which is the product of the total kinetic energy of a rainfall and the maximum 30-minute rainfall intensity, reflecting the ability of rainfall to detach soil, form runoff and transport sediment. Accurate values of rainfall erosivity depends on high temporal resolution rainfall data, and regional water erosion assessment needs high spatial resolution rainfall erosivity data. Current available grid precipitation datasets with both high temporal and spatial resolution make this possible. This study selected four datasets from year 2001 to 2020, GPM (The Final Run V06B Integrated Multi-satellite Retrievals from Global Precipitation Measurement) 30min and daily rainfall with 0.1° grids, ERA5 (an enhanced global dataset for the land component of the fifth generation of European ReAnalysis) 60min and daily rainfall with 0.1° grids, to calculate and then to evaluate the accuracy of average annual erosivity estimation by comparing the calculations with 60min rainfall data from 2399 weather stations over mainland of China. When grid datasets were used directly in erosivity equations, the calculated results of the four data sets were obviously low with the GPM data better than the ERA5 for both daily and 30min data, but there were regional differences. The 30 or 60min results were significantly lower than the daily results, which means the grid data might reduce local rainfall heterogeneity under high temporal resolution conditions, and could not be directly used. After developing a conversion coefficient by regressing annual erosivity calculated with four datasets to that with 60min rainfall data from weather stations. The annual erosivity values of four datasets were improved with 0.862 and 0.667 of Nash coefficients for GPM and ERA5 daily data respectively and 0.893 and 0.746 for 30min or 60min data respectively. This study proved the potential abilities of four grid precipitation datasets in estimation of average annual erosivity with high spatiotemporal resolution, and provided a calibration method by using local measured precipitation data.

#### THE USE OF RUSLE MODEL AND BATHYMETRIC SURVEY TO UNDERSTAND SOIL EROSION AND RESERVOIR SEDIMENTATION

C. NISTOR <sup>1</sup>, I. SAVULESCU <sup>1</sup>, G. TOROIMAC <sup>1</sup>, S. CARABLAISA <sup>2</sup>

<sup>1</sup> University of Bucharest, Faculty of Geography, Department of Geomorphology-Pedology-Geomatics, Bucharest, ROMANIA

<sup>2</sup> Orsova Research Station, Orsova, ROMANIA

The aim of the paper was to compare the sediment transferred by a river catchment to the sediment volume accumulated at the river mouth. First, the sediment transferred was estimated in GIS based on the soil loss according to the RUSLE model further integrated into the sediment production equation. Then, the sediment volume accumulated at the river mouth was estimated by the diachronic overlap of topographic and bathymetric data. This methodology was validated for a case study in South-Western Romania, in the temperate climate with Mediterranean influences. Following the Iron Gate I Reservoir construction on the Danube River, the water level increased upstream and flooded river mouths. Small “gulfs” formed as in the case of the Eselnita River. Despite the extended forest cover, the Eselnita catchment is prone to erosion due to the high slope, sandy soils, and intense rain events. For the Eselnita catchment case study, the sediment production obtained by the RUSLE model corresponds to about 70% of the sediment volume accumulated at the river mouth during 53 years. The distribution of sediments indicates the prevalence of the sediments transported by the Eselnita River and a lesser input of alluvium washed from the slopes directly into the lake. The difference in sedimentation may be due to human activities on the river mouth banks to extend the built-up area and enjoy the waterscape. The RUSLE model enabled the identification of locations with a high potential for erosion, influenced by land use, soil properties, rainfall and runoff impacts, relief morphometry and anthropogenic activities. The highest erosion potential indicated by this equation corresponds to the strongest anthropogenic pressures introduced into the land by overlapping many activities. Sediment production depends on the transfer function, which is strongly influenced by the distance to the channel of each cell in the subbasins and is greatest for close cells with near-instantaneous discharge.

#### ASSESSMENT OF SOIL WIND EROSION IN THE PAN-THIRD POLE REGION

Y. QINKE, Y. XUYAN, W. CHUNMEI, P. GUOWEI, W. LEI, L. YONGQING

Northwest University, Xi'an, CHINA

The Pan-Third Pole region (PTP) (covering an area of approximately  $5.14 \times 10^7$  km<sup>2</sup>) is ecologically fragile, with intense soil water and wind erosion making greater threats to the socio-economic development of the region. An accurate assessment of wind erosion is the basis for soil conservation. Soil wind erosion in the PTP from 1982 to 2020 was calculated using the RWEQ, based on meteorological, soil, topographic, and vegetation indices data. The results showed that: (1) Soil wind erosion in the PTP mainly occurs in cropland and grassland in semi-arid areas, and aeolian landform as natural landscapes primarily occurring in extremely arid and arid areas, the average wind erosion rate is  $633.65 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , of which the mean soil wind erosion rate in the area where wind erosion rate is greater than  $50 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$  is  $4,316.94 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , for cropland, grassland, and scrubland were  $1,981.14 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ ,  $3,815.05 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , and  $4,010.95 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , respectively. (2) From 1982 to 2020, the soil wind erosion rate in the PTP decreased by  $10.61 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ . The proportions of area with decreasing and increasing trends were 19.53% and 28.35%, respectively. (3) Soil wind and water combined erosion mainly occur in the northern of Syria, the Indus River Plain, the northern border of Iran and Afghanistan, the southwestern of the Qinghai-Tibet Plateau, central Mongolia, the central of the Loess Plateau, Inner Mongolia, and the bordering areas of the three eastern provinces, the average soil erosion rate is  $4,534.77 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , for grassland and cropland being  $4,752.41 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$  and  $1,495.68 \text{ t} \cdot \text{km}^{-2} \cdot \text{a}^{-1}$ , respectively. This study provides a more comprehensive knowledge of soil wind erosion in the PTP, and will support the soil conservation planning, and global soil erosion mapping. However, further study is needed to evaluate the reasonableness and uncertainty analysis of the mapping, and the interaction between water and wind erosion.

Soil erosion mapping serves various purposes, the most significant one is to support soil conservation. Small-scale mapping aims to choose soil conservation practices, while at large scale, is to determine soil conservation needs. This study targets soil erosion assessment and regional scale mapping from the soil conservation perspective. By analyzing existing soil erosion maps across different scales, we clarified that the main content of regional-scale erosion mapping focused on the proportion of soil loss area, which referred to the percentage of the area with soil erosion rate exceeding the soil loss tolerance. Two methods employed at the regional scale for the above issue include sampling and grid-based methods. The former provides high accuracy at the sampling units while having uncertainties in spatial distribution. The grid-based method ensures full coverage of the entire region, thus benefitting spatial distribution. However, due to the challenges of obtaining high-resolution input factors for large areas, the accuracy of the results is insufficient to meet the requirements. To address the above issues, this study employed a stratified unequal probability systematic spatial sampling method to conduct regional erosion assessment, with detailed erosion factors investigated within each sample unit. Over 50,000 units were explored in China and 64 neighboring countries. The Chinese Soil Loss Equation (CSLE) was used to calculate the proportion of soil loss area and averaged erosion modulus for each sampling unit. The results were validated through field surveys, 137CS measurements, and runoff plots. An upscaling method was explored to upscale the soil erosion assessment results from the sampling units to regional scales. As a result, spatial distribution maps of the proportion of soil loss area and erosion modulus were generated for the whole region, providing a clear understanding of the areas and spatial distribution that require soil conservation practices. This study may provide a methodological and data reference for global soil erosion mapping.

#### AERIAL PHOTOGRAPHS AS A TOOL FOR DETERMINING THE SOIL ORGANIC CARBON STOCKS VARIABILITY RESULTING FROM EROSION PROCESSES. PRELIMINARY STUDIES IN MORAINIC AREAS OF NORTHERN POLAND

M. SWITONIAK, K. MILEWSKA

NICOLAUS COPERNICUS UNIVERSITY, TORUN, POLAND

Soil erosion is one of the main factors leading to the redistribution of soil organic carbon (SOC) pools in the humus horizons. Truncation of soils located on the tops of hills and in the upper parts of slopes and the accumulation of humus material in footslope/toeslope position leads to changes in the properties of surface soil horizons like texture, colour or humus content. The aim of study is to assess the SOC stocks in humus horizons of agricultural soils in the context of their diversity resulting from erosional transformations visible on aerial photographs. SOC pools were calculated for 139 soil profiles located within arable moraine plateaus of Northern Poland. The most heavily truncated Regosols (summits of hills - light brown in the aerial photos) had resources of SOC at  $2.5 \text{ kg}\cdot\text{m}^{-2}$ . The clay-illuvial soils with argic horizons (mostly Luvisols) are most common in the research area. The average carbon stocks in these soils were  $3.28 \text{ kg}\cdot\text{m}^{-2}$ . In the group of eroded clay-illuvial soils located in upper, convex parts of slopes and with brown colours of surface horizons (due to the exposure of argic horizons on the surface) this amount decreased to  $1.40 \text{ kg}\cdot\text{m}^{-2}$ . Non-eroded or slightly truncated pedons of clay-illuvial soils characterized by a light brown color and location in the middle and lower part of the slopes had  $4.11 \text{ kg}\cdot\text{m}^{-2}$  of SOC stocks. In areas with poor drainage Gleyic Chernozems and Gleysols with well developed and very dark on aerial photos humus horizons dominated. In non-eroded pedons with such dark A horizons SOC resources were about  $10.6 \text{ kg}\cdot\text{m}^{-2}$ . There were also spots of a lighter color on aerial photos, where soils with SOC stocks at  $6.8 \text{ kg}\cdot\text{m}^{-2}$  were slightly shallowed by erosion. The accumulation of slope materials in the depressions led to an increase of SOC stocks to the  $15.2 \text{ kg}\cdot\text{m}^{-2}$ . The conducted research indicates considerable possibilities of aerial photos application in creating detailed maps of the SOC stocks.

**Keywords:** arable soils, soil organic carbon stocks, erosion, Luvisols, Chernozems

<sup>5</sup> Dartmouth College, Hanover, USA

<sup>6</sup> Syracuse University, Syracuse, USA

<sup>7</sup> Virginia Tech, Blacksburg, USA

Accelerated soil erosion and deposition processes pose major threats to soil health and ecosystem services in forested landscapes, particularly following intensive practices such as whole-tree harvest. These disturbances drastically alter soil dynamics, leading to increased soil erosion and deposition rates, which subsequently affect soil properties and carbon storage. At the Hubbard Brook Experimental Forest (HBEF) in NH, USA, a whole-tree harvest experiment was conducted from 1983-1985 in a small watershed to evaluate the long-term impacts of deforestation on the carbon budget, soil properties, cycling of nutrients, and vegetation regrowth. Our prior study at HBEF assessed the impact of whole-tree harvesting on soil redistribution rates using 239+240Pu and found concerning erosion rates and deposition rates. Those findings represent an average of approximately 60 years of redistribution processes. However, information on how soil redistribution rates have evolved after whole-tree harvesting in northern hardwood forests is still missing. In this study, we aim to examine the long-term effects of whole-tree harvest on soil redistribution rates by using 239+240Pu and re-sampling approach. We expect to understand how soil erosion and deposition rates have changed since the deforestation. We hypothesize that soil redistribution rates were initially higher and decreased rapidly, influenced by the swift regrowth of bushes and trees in the years following deforestation. To assess soil redistribution rates, we employed a re-sampling approach combined with the use of 239+240Pu isotopes as soil erosion tracers. Samples were initially collected in the years 1983 (pre-deforestation), 1986, 1991, 1998, and 2022. The soil subsampling from the HBEF archive occurred in November 2023. The samples have been analyzed for 239+240Pu isotopes, and our next steps include calculating Pu inventories and determining the rates of soil erosion and deposition. By elucidating the temporal patterns of these redistribution processes, we will be able to better predict the recovery timeline of the hillslopes. This knowledge is crucial for developing forest management practices aimed at preserving soil health and enhancing carbon storage.

<sup>3</sup> Northwest A&F University, Yangling, CHINA

Vegetation cover is a crucial factor affecting soil erosion, and its high-precision mapping plays a considerable role in assessing regional soil erosion. In the Chinese Soil Loss Equation (CSLE), the Vegetation and Biological Practice Factor (B factor) reflects the impact of forest and grass canopy cover and ground cover on soil erosion. Canopy cover is calculated using NDVI to determine the Fractional Vegetation Cover (FVC), while ground cover is calculated either through field surveys or using Non-Photosynthetic Vegetation (NPV) cover, obtained through the Pixel Tripartite Model inversion. This study employed slightly different methods to obtain ground cover of arbor forest for different growth seasons in three projects: the Qinghai-Tibet Plateau, China, and the Pan-Third Pole region. (1) In the Qinghai-Tibet Plateau and Pan-Third Pole region, arbor forests were divided into evergreen and deciduous categories. Evergreen forests were assigned values based on the relationship between canopy cover and ground cover, while deciduous forests used NPV cover in winter. (2) In the project of China, ground cover from sampling points was combined with observed annual variations in ground cover for calculation. Both methods yielded satisfactory results. Based on the calculated canopy and ground cover, B factor was finally computed at both the survey unit scale and regional scale, which can be directly used in the soil erosion model to calculate the soil erosion rate. The successful implementation of these methods not only provide practical solutions for regional B factor mapping but also offer important data support for the mapping of global soil erosion.

**Keywords:** Soil erosion, vegetation cover, Biological practice factor, CSLE/USLE, soil erosion model

#### EFFECT OF UNDERSOWN CROPS AND STRIP TILLAGE AT REDUCING SEDIMENT AND PESTICIDE SURFACE LOSSES IN MAIZE CROPS

T CLEMENT<sup>1</sup>, C L BIELDERS<sup>1</sup>, A DEGRE<sup>2</sup>, G MANSSENS<sup>3</sup>, G FOUCART<sup>3</sup>, O PIGEON<sup>4</sup>, A BLONDEL<sup>4</sup>, B HUYGHEBAERT<sup>4</sup>

<sup>1</sup> UCLouvain Earth and Life Institute, Louvain-la-Neuve, BELGIUM

<sup>2</sup> ULiège Gembloux Agro-Bio Tech, Gembloux, BELGIUM

<sup>3</sup> Centre Indépendant de Promotion Fourragère, Louvain-la-Neuve, BELGIUM

<sup>4</sup> Centre Wallon de Recherches Agronomiques, Gembloux, BELGIUM

Soils of the European loess belt are susceptible to runoff and erosion when intensively cultivated. Besides the loss in soil resources, the transfer of runoff, sediment and pollutants from cropland threatens the quality of surface water bodies, and causes muddy floods damaging rural infrastructure. To alleviate such externalities, we assessed the effectiveness of two cropping practices at mitigating water, sediment, and pesticide surface flows in maize crop by means of erosion plots under natural rainfall during the 2021, 2022 and 2023 cropping seasons. Conventionally tilled sole maize crop (control) was compared to 1) maize with red fescue or white clover sown in the inter-row at the same time as maize and 2) maize sown under strip-tillage, which consists in tine-tilling the maize row only, leaving inter-row undisturbed. All treatments were implemented in triplicate, on two trial sites each year. Results from the undersown plots showed no significant difference in seasonal runoff, soil and pesticide (sulcotrione) losses compared to the control practice, on any of the trials. This is because most soil and pesticide losses occurred in the spring, when both the undersown crops and maize were still poorly developed. When strip tillage was performed after a well-developed winter cover crop, and excluding trials with very low magnitude in surface flows, a statistically significant difference ( $p < 0.1$ ) between strip-tillage and the conventional practice was observed regarding seasonal runoff (mean mitigation effect of -69%), soil (-85%) and sulcotrione (-66%) losses. In contrast, when strip-tillage was performed on bare soil or after a poorly-developed winter cover crop, no significant differences were observed. Given that the success of strip-tillage in terms of surface flow mitigation appears closely related to the development of the previous winter cover crop and its effect on soil structure, a future albeit challenging avenue could lie in the use of a process-based model to identify the environmental and cover crop management conditions that would ensure a high mitigation effectiveness of strip-tillage.

#### PROPOSAL AND PURPOSE OF A DATABASE FRAMEWORK OF CLIMATE CHANGE MORPHO-SEDIMENTARY MARKERS FROM TEST SITES OF SOUTHERN ITALY

V. AZZILONNA, L. CONTILLO, G. CORRADO, P. GIANNANDREA, M. SCHIATTARELLA

Università degli studi della Basilicata - Dipartimento delle Culture Europee e del Mediterraneo, MATERA, ITALY

Climate changes in the Mediterranean area over the last 200 years followed the end of the Little Ice Age. In the last decades, global change effects are also affecting large parts of internal and rural areas of southern Italy. For example, climate seems to be a major driving factor, as well as human factors, in the recent fluvial dynamic evolution in several Italian regions. Very fast climate and environmental changes are impacting river systems inducing assessable morphological variations. Further, the intensity of extreme rainfall events represents trigger and driving factor for fluvial erosion and mass-wasting processes, in terms of efficiency and rates, which affect the slope stability in badland areas.

Erosion rates of landforms characterized by complex hydro-geomorphological dynamics, intense erosion processes, and sediment yield, are valuable for the understanding of soil erosion processes and geomorphic changes due to extreme events. Similarly, river systems provide a potential record of landscape evolution in a particular climatic framework. So, measuring geomorphic parameters means monitoring and understanding river evolution over time.

The analysis of some categories of markers, such as the geomorphological and sedimentary ones, in key areas where climate changes may cause environmental hazard seems a best practice for the territory safeguard. Geomorphological and sedimentary markers of climate change in rural areas of Basilicata, referred to both streams and slopes, are here listed:

- channel bed modifications;
- accelerated erosion landforms/soil erosion processes;
- drainage density variations;
- erosion rates;
- sedimentation rates;
- sediment connectivity evolution;
- rainfall/temperature multi-temporal values; dry/wet periods distribution; flood events frequency.

These parameters can be measured by applying different techniques (direct or indirect – field surveys, Internet-of-Things, DoD, remote sensing techniques, historical data), using appropriate spatial (from channel to catchment) and temporal scales (long-, medium- and short-term monitoring). Such a multi-scale approach will provide different inputs for the understanding of evolutionary trends, aiming to provide an operational protocol for the climate change impact assessment approach.

Soil erosion and land degradation are among the main threats to agricultural landscapes such as Mediterranean agroecosystems. Assessing the variety of geomorphic processes at the different spatio-temporal scales must be considered for identifying hotspots of sediment dynamics, as to support decision-makers in a sustainable watershed management. However, there is a lack of integrated methods that combine geomorphic spatial data with a comprehensive approach to sediment dynamic modelling.

Therefore, we introduce a novel methodology that integrates geomorphic data derived from a detailed digital mapping with structural and functional components of sediment connectivity. In particular, a new GIS-based model named HOTSSED was developed, designed to assess potential hotspots of sediment sources and related dynamics at the watershed scale.

We tested our approach in an agricultural-forested watershed in the Northern Apennines (Italy), starting with the elaboration of an Inventory Map of sediment sources. Then, we estimated the geomorphic potential of sediment sources with a relative scoring system. Moreover, we simulated the structural sediment connectivity and the sediment transport potential by combining terrain/hydrological parameters, land use data, and rainfall erosivity. Finally, the integration of these components was achieved through a raster-based calculation method.

HOTSSED provides a holistic assessment of sediment sources and related dynamics allowing to detect emergent properties of the landscape through a unique and intuitive output. The results show that the model successfully identified hotspots associated with complex and polygenetic geomorphic systems. They are located in areas close to the main channels, which mostly include processes like rill-interrill and badland erosion and/or landslides associated with bank erosion. Moreover, it identified areas prone to store sediments in depositional landforms with low geomorphic potential and low connectivity.

HOTSSED offers a valuable tool supporting decision-makers towards a sustainable watershed management. Moreover, the identification of hotspots of sediment sources allows for a preliminary evaluation of the contribution of different processes to sediment dynamics using sediment fingerprinting (e.g., unravelling lithological and land use features as controlling factors).

**SEDIMENT CONNECTIVITY AND FRACTALS: AN APPROACH TO EXPLORE WATER EROSION DYNAMICS**

F. BARBADORI, S. PELACANI, T. GRACCHI, C. TACCONI STEFANELL, G. ROSSI, F. RASPINI

University of Florence, Florence, ITALY

Water erosion sets a significant contemporary challenge, particularly in hilly areas, where surface runoff can mobilize large amounts of sediment to rivers. Assessing potential soil erosion involves studying relationships between sediment sources and sinks within a watershed (i.e. sediment connectivity). Sediment connectivity involves both structural and functional aspects and can be evaluated using specific indexes such as the Index of Connectivity (IC). Conversely, suspended sediment transport processes are intermittent and fluctuate across various temporal and spatial scales, making it difficult to create predictive models without a site-specific calibration. To overcome this problem, in this study, a data-driven approach for two years monitoring of streamflow (Q) and suspended sediment (SS) was applied for automating the classification of event-based sediment dynamics through machine learning. For each storm event, sediment connectivity was calculated, and the link between sediment transport and deposition was defined by treating SS as a fractal system to describe and predict patterns in SS dynamics across different temporal scales. Analyses of Q, SS and associated grain size distribution were conducted at the event base resolution, considering their probability distribution functions, Fourier power spectra, and machine-learning classification of hysteresis index. The study area was a 1 Km<sup>2</sup> agricultural watershed located near Florence (Italy), characterized by different land cover and first-order mixed bedrock alluvial stream channels. High-resolution mapping with a Drone LIDAR scanner and a submersible particle size analyser (LISST) allowed long-term measurement of suspended particle size and volume concentration. Preliminary results highlighted a robust correlation between sediment connectivity, land cover and sediment transport. Q-SS information flows exhibited seasonally varying behaviour aligned with dominant runoff generation mechanisms from wet to dry seasons. However, runoff timing and magnitude reflected significant catchment heterogeneity attributable to baseflow contributions from different lithologies and variations in preferential flow paths (land cover). In conclusion, this study analyzed a small catchment area in terms of sediment connectivity and related sediment transport relations, identifying potential (dis)connectivity areas in the basin.

<sup>4</sup> Department of Science, Roma Tre University, ROME, ITALY

The EU Soil Strategy for 2030 states that it is essential to step up efforts to protect soil fertility, reduce soil erosion and increase soil organic matter by adopting sustainable land management practices. The recently proposed Directive on Soil Monitoring and Resilience Law would enforce the soil erosion monitoring on a regular basis. Italy, due to its climate and geo-morphology, is one of the European countries most affected by soil erosion, therefore it is critical to implement locally tailored land management actions that mitigate/revert soil losses by erosion.

Modeling can provide a quantitative and consistent approach for estimating soil erosion and sediment yield under current and alternative scenarios. However, due to the geo-morphological and land use heterogeneity of the Italian territory, the granularity of the erosion data must be adequately fine to model field-scale mitigation scenarios.

In the current study, the RUSLE equation was applied to the Lazio region by leveraging locally produced, high spatio-temporal resolution datasets. The study region, due to its high annual rainfall intensity and presence of rolling landscapes, is an excellent pilot area to assess the potential of erosion mitigation strategies. The modeling framework that we built-up can count on:

- a novel, high-resolution (5m) Digital Terrain Model was developed;
- the erosivity factor was estimated from an effectively distributed network of rainfall sensor acquiring at high frequency for 88 stations (covering the period 2012-2023);
- a very high-resolution (0.2m) map of land use-land cover, generated by photointerpretation, was used and complemented with information on arable land from farm documentation;
- a locally produced soil map was used to estimate the influence of the soil properties on the erosional process.

This bottom-up approach supported the development of a novel, 10m resolution RUSLE-based map that allowed the assessment of the soil erosion at the farm level. This can provide support to the CAP Strategic Plan 2023-2027 and the proper application of GAEC to mitigate the erosion severity.

#### SOIL EROSION IN FORESTS: EFFECTS OF PLANT DIVERSITY, TREE TRAITS AND BIOLOGICAL SOIL CRUSTS

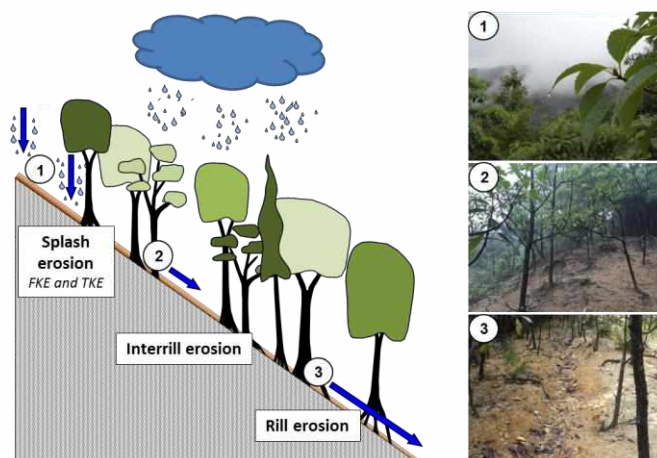

S. SEITZ<sup>1</sup>, C. GALL<sup>1</sup>, P. KÜHN<sup>1</sup>, Z. SONG<sup>1,2</sup>, X. SHI<sup>2</sup>, T. SCHOLTEN<sup>1</sup>

Soil erosion remains a major environmental problem globally, and it is widely accepted that forest cover is a key factor to mitigate degradation. However, severe soil losses can be observed in woodlands, particularly after disturbances. Trees provide a multi-layered canopy which largely affects precipitation patterns. Forest floor cover by plants or plant litter further influences raindrop impacts. The way in which these plant communities and characteristics interact and can mitigate, but also intensify, erosion has been little studied. Here, we summarize results on effects of species diversity, identity, functional traits and the soil covering layer including soil fauna on throughfall and interrill erosion in subtropical, temperate and mediterranean forest ecosystems.

Results show that plant covers do not necessarily have a protective effect against soil erosion and that high rates of sediment and nutrient discharge can occur under forest. Species identity affects initial erosion processes and erosion-promoting and -mitigating species can be clearly identified. That also applies to the leaf litter cover, where single species show varying influences on discharge and are further affected by soil mesofauna. Therefore, the appropriate choice of tree species during the establishment of reforestations plays a major role for erosion control. Moreover, functional tree traits affect soil erosion rates. High crown cover and leaf area index reduce erosion, whereas it is enhanced by increasing tree height. Throughfall kinetic energy is minimized by low leaf area index, low tree height, simple pinnate leaves, a high number of branches and a low crown base height. Higher tree species richness can reduce sediment discharge, although this effect is less pronounced in early successional forest stages. Moreover, biological soil crusts importantly mitigate sediment discharge and runoff generation in forest environments and this effect varies tremendously with specific traits. It can be concluded that the ability of biological soil crusts to quickly colonise soil surfaces after disturbance are of particular importance for soil erosion control under forest.

<sup>5</sup> LVIA, Lay Volunteers International Association, Nacala, MOZAMBIQUE

<sup>6</sup> IHE Delft institute for Water Education - Department of Land and Water management, Delft, THE NETHERLANDS

The coastal city of Nacala, Mozambique has been suffering from extreme soil erosion for decades. In the context of a complex socio-economic conditions, the urban area has been growing uncontrolled and without a proper drainage system. Informal settlements have been constructed on the steep sandy erodible soil of the Nacala's Peninsula. When a relatively extreme rainfall event occurs, even a moderate flood can develop gullies of several meters of depth along the unpaved streets or other paths, posing serious risk to people, buildings and infrastructures (see example in the picture below, taken in December 2022). There is an urgent need to make explicit the potential impact of urbanisation on soil erosion, either by creating awareness about the main drivers and by finding effective solutions with the cooperation of the local inhabitants. In the context of the project "Participa no Desenvolvimento!", a CSO-LA project funded by the European Commission, we explored sustainable measures to prevent erosion. Using a geographic information system (GIS) approach, including the calculation of a spatially-distributed urban-corrected stream power index (SPI), we demonstrated that the rapid urbanisation of the city during the past decades is the main reason for the increased erosion. Moreover, we showed that the high shear stress over the loose soils would require extensive and expensive structural interventions to stabilize the slopes and the formed gullies. Therefore, we selected and pre-designed nature-based and sustainable solutions to prevent erosion. The implementation of the measures should involve the local population and consisted in a combination of:

- reforestation of the remaining bare lands to prevent further soil erosion;
- stabilization of channels with suitable endemic plants;
- proposing a plan of extensive rooftop rainfall collection .

An open-source PCRaster processing tool to calculate the urban-corrected SPI has been developed and made available in QGIS. Particularly, the rooftop rainfall collection measure has been tested with the urban-corrected SPI showing a considerable reduction in erosion potential of the flow.

#### MULTI-TEMPORAL ASSESSMENT OF LAND AND SOIL DEGRADATION DUE TO CHESTNUT MANAGEMENT FROM HYPERSPECTRAL AND MULTISPECTRAL SATELLITE DATA

N. MZID <sup>1</sup>, F. TERRIBILE <sup>1,2</sup>

<sup>1</sup> Department of Agriculture, University of Naples Federico II, Portici, ITALY

<sup>2</sup> CRISP Research Center, University of Naples Federico II, Portici, ITALY

Italy is among the main European producer of chestnut, where Campania region provides about 50% of the global production nationwide. Chestnut management vary among countries, although coppicing stands for the most intriguing technique. Assessing how forests react to this technique is key to develop sustainable practices. Coppicing management in chestnut present evidence of soil erosion and land degradation, due to the type of management which include dragging the trunks over soils truncating fertile topsoils.

PRISMA satellite, symbolizes an evolution in earth observation knowledge and opens new prospects to advance hyperspectral data development in forestry applications. The objective of this study is to assess based on hyperspectral and multispectral sensors the: (i) bare soil presence, indicating where and when a pixel was detected as bare surface in a representative forest area, (ii) a clearcut map separating areas caused by coppice treatments from other bare soil occurrence causes, and (iii) impacts of chestnut management on land and soil degradation.

A multi-temporal approach was developed to select bare soil pixels along a satellite time series of five years for both PRISMA and Sentinel-2 data in the regional forests of Campania (Italy). The approach consists of a filtering process for each image, based on selective indices and thresholds, to detect and exclude green and dry vegetation, so keeping only bare soil pixels. The temporal trends of the Normalized Difference Vegetation Index and Leaf Area Index were assessed in bare soil areas caused by coppice treatment, after recognition and delineation. Afterwards, we analyze the spectral signal from forest clearcut areas, comparing it to the spectral signature of uncut forest area, and erosion-affected sites caused by chestnut managements. The notable change in the increment differences between yearly maximum NDVI and LAI defined the spatio-temporal changes of the coppice treatment over the years. We conclude the usefulness of PRISMA sensor to monitor and map bare soil occurrence under coppice managed areas from multi-year imagery in Italian forests.

Soil degradation is a process primarily triggered by hydric erosion, coupled with overexploitation and inadequate land and soil management, expected to increase in the following 25 years. By 2050, it is projected that 90% of the world's soils will be severely degraded, emphasizing the urgent need to identify vulnerable areas and implement soil recovery practices. Using spatially explicit methodologies is a helpful, cost-effective tool for monitoring soil hydric erosion (SHE), allowing large-scale estimations over multiple years. In this study, we used the Revised Universal Soil Loss Equation (RUSLE) to quantify SHE related to landcover change (LCC) in Chile between 2001 and 2020 across arid, mediterranean, temperate, and cold climates. Using Generalized Additive Models (GAMs), we identified key factors influencing the calculated annual SHE rates. Our model determined a national average erosion rate of 222.289 (Standard Dev = 189.921) tonha<sup>-1</sup> yr<sup>-1</sup> and net 93,834,163 ton yr<sup>-1</sup>. We also identified a cyclical trend in SHE, which considers further evaluation. Topography was the primary factor influencing national SHE. The R factor (erosivity) emerged in the Mediterranean climates, and the C factor (vegetation resistance) in Temperate and cold climates. Significantly, landcover types such as croplands and exotic forestry contribute to SHE irrespective of latitudinal variation. Based on our findings, we propose management strategies aiming to mitigate the impacts of landcover and SHE, seeking to alleviate the negative effects of landcover influence. Finally, our study contributes to SHE monitoring because it provides a unique historical perspective on soil degradation, applicable to Chile and worldwide.

<sup>2</sup> LaMMA Consortium, Sesto Fiorentino, Florence, Sesto Fiorentino, ITALY

<sup>3</sup> Department of Geosciences, University of Padova, Padova, ITALY

Water erosion is one of the most widespread forms of soil degradation and it is expected to increase as an effect of global change, especially due to the amplified frequency of extreme and localised rainfall events. Focusing on the Mediterranean region, where these phenomena produce the most catastrophic erosion, this research aims to model soil erosion focusing on rainfall spatial distribution using precipitations as detected by weather ground-radar upon an analysis of rainfall-cell patterns at regional scale (Tuscany, Italy)

Precipitations were elaborated by adopting a kriging method processing CAPPI (Constant Altitude Plan Position Indicator) reflectivity and rain gauges rainfall with an External Drift Kriging (KED) over a 30' time-step frames and 5' conditional merging images based on elaborations made available by DPCN (Italian National Civil Protection Department). Soil erosion was modelled using the platform based on the soil erosion/landscape evolution model LandSoil under Python coding simulating runoff combining a cinematic wave using St.Venant equations with a conceptual "bucket" model for infiltration, and a two-level sediment redistribution process for rill and inter-rill erosion on a sediment concentration protocol.

Soil erosion was simulated over a selection of rainfall events from the last ten years. Results are illustrated through a combined representation of factors that considers: 1) The land surface affected by the storm (i.e., rainfall-cell subjected to runoff), 2) The involved rainfall energy and erosion rate of the processes, 3) The sediment yield delivered over the erosive event. Such approach, applied to seasonal analysis, opens-up to a methodology for analysing the spatial extent of the rainfall and the erosive effects at ground. Drifts in erosion could be also detected by the use of long-terms rainfall series and return-time of the erosive events, useful to inspect the evolution of the processes due to climate change.

<sup>4</sup> European Commission, Joint Research Centre (JRC), Ispra, ITALY

Healthy soil is essential for agriculture and ecosystem functioning. Changes in soil quality have an impact on the delivery of critical ecosystem services such as food production, water supply, and regulation. Soil erosion is notoriously ephemeral because it is dependent on the nexus of vulnerable soil, weather, and antecedent moisture levels; particularly the occurrence of climate extremes, such as big strong rainfall episodes or droughts with wind. When the right mix of events occurs, positive feedbacks can lead to erosion striking with disastrous environmental and socio-economic consequences. A situation that makes it important to better identify locations where multiple concurrent soil erosion processes may occur.

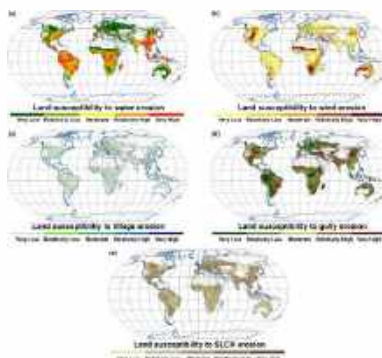

In this presentation we discuss (i) the geography of soil loss by water, wind, tillage, and crop harvesting erosion; (ii) their possible co-occurrence at EU (Borrelli et al., 2023a) and globally scale (Borrelli et al., 2023b); and (iii) how to better integrate research on soil erosion to improve modeling performances and to support decision-makers in both ex-ante and ex-post policy evaluation.

Acknowledgement. This presentation is part of the project “Accelerating collection and use of soil health information using AI technology to support the Soil Deal for Europe and EU Soil Observatory” (AI4SoilHealth) that received funding from the European Union’s Horizon Europe research and innovation programme under grant agreement No. 101086179.

#### ESTABLISHING THE CONCEPT OF TOLERABLE SOIL LOSS CONSIDERING EPISODIC EVENTS

M. BAUER<sup>1</sup>, T. DOSTAL<sup>1</sup>, J. KRASA<sup>1</sup>, P. KAVKA<sup>1</sup>, J. KAPICKA<sup>2</sup>, V. KOLBABOVA<sup>2</sup>, A. ACHASOVA<sup>2</sup>

<sup>1</sup> Czech Technical University in Prague, Prague, CZECH REPUBLIC

<sup>2</sup> Research Institute for Soil and Water Conservation, Prague, CZECH REPUBLIC

The established soil erosion protection in the Czech Republic is based on the long-term average values and only aims to protect the sustainability of agricultural production. Beyond that, however, real damage occurs episodically with on-site and off-site impacts, the consequences of which must be remediated. It is therefore important to ask whether the definition of the concept of tolerable soil loss is correct and where the limit should lie. To answer this question, the measured volumes of soil loss and the damage they cause need to be compared with the system of limits currently in use. For this purpose, an analysis of the available measured data on soil loss in the Czech Republic was carried out. The results show that soil loss varies depending on the form of erosion and that for higher forms of erosion the tolerable soil loss is significantly exceeded even for a single erosion event. These results are important for understanding the erosion process in the affected areas and for establishing a comprehensive system of soil loss limits.

This research was funded by Technology Agency of the Czech Republic, grant number SS05010180 and European Union's Horizon 2020 research and innovation program grant agreement No 101000224.

#### ARABLE SOIL RESISTANCE AGAINST EROSION SHIFTS IN RESPONSE TO EXTREME WINTER RAINFALL

H.R. UPADHAYAY, A. JOYNES, A.L. COLLINS

Net Zero and Resilient Farming, Rothamsted Research, Okehampton, North Wyke, UNITED KINGDOM

The health and resilience of aquatic environments are declining due to excessive sediment flux associated with land use. Land use and rainfall interactions drive temporal shifts in suspended sediment sources, but the magnitude of such changes remains poorly understood due to the lack of land-use specific source tracers. In this study, we applied  $\alpha,\omega$ -dicarboxylic fatty acids (diFAs)-root-specific biomarkers, as diagnostic tracers for apportioning sources of time-integrated suspended sediment samples collected from a grassland-dominated agricultural catchment in the southwest of England during the wet winter period. Applying diFA-specific stable carbon isotope analysis and a Bayesian isotope mixing model, we show stream banks contributed most of the sediment in the early winter, i.e., October–December, (90% credible interval (CI) ranging from 44% to 79%) while winter cereal-dominated arable land contributed more than half (90% CI: 35% to 85%) of the sediment during the late winter, i.e., January–March. The dominant sediment source shifted in conjunction with a period of prolonged consecutive rainfall days in the later period, suggesting that arable land loses its resistance against erosion once the soil gets saturated. Our novel findings demonstrate that diFAs isotopic signatures are promising tracers for understanding the resistance of agricultural soils to water erosion and quantifying the interactive effects of extreme rainfall and land use on catchment sediment source dynamics.

A devastating flash flood occurred in the Vernazza catchment, Cinque Terre, Liguria, Italy, on October 25, 2011, resulting in numerous landslides and severe soil erosion, causing both fatalities and economic losses in the millions of Euros. The region, known for its terraced landscape and steep slopes, features mostly abandoned terraces that were historically used for vine and olive production. Interconnected processes exacerbate each other, leading to slope degradation, particularly affecting the abandoned terraced areas.

In our study, we employed the Limburg Soil Erosion Model (LISEM) to investigate the dynamics and potentially impacted areas concerning the source, transport, and deposition of sediments. LISEM utilizes detailed information on soil, topography, and land use. The model was applied at a 1m scale, incorporating climatic data from two nearby weather stations and field-collected soil geotechnical properties. LISEM evaluated hydrological dynamics and processes related to surface runoff, including soil erosion and landslides associated with soil water content. The results delineate the spatial distribution of soil erosion processes and landslides. Additionally, we delineate sediment transport pathways and depositional zones. These findings aid in identifying critical areas requiring interventions, especially recognizing abandoned terraces susceptible to collapse. Therefore, our LISEM approach provides crucial information for basin managers, farmers, and environmental protection agencies.

<sup>2</sup> Department of Soil Physics and Water Management, Institute for Soil Sciences, HUN-REN CAR, Budapest, HUNGARY

<sup>3</sup> National Laboratory for Water Science and Water Safety, Budapest, HUNGARY

Based on more than 110 years of expertise in soil profile exploration, description and soil mapping, Hungary is a major power in the field of soil data in Europe and even in the world. The development of commercial agriculture in the 1950s and 1960s and the spread of modern nutrient management and agriculture required increasingly detailed and information-specific soil maps. In our country, soil mapping work developed in the 1980s, leading to the preparation of genetic soil maps at a scale of 1:10,000 for two-thirds of the country. The digitisation and program-level processing of national map data recorded on paper has not been done until today.

A high spatial resolution soil database is under development in Hungary consisting of legacy soil observation data originating from different soil surveys. In the course of our work, soil information is collected for selected sample areas in Hungary (Lake Balaton, Lake Fertő and Lake Velence catchment, Csongrád-Csanád County). The vectorisation of the soil data has resulted in the Profile-level Database of Hungarian Large-Scale Soil Mapping (Hungarian acronym: NATASA), which contains currently data on 148,000 soil layers from about 37,000 soil profiles. These data include field survey descriptions and laboratory measurements.

The geospatial processing of soil profile data and their transformation into target maps, featuring soil physical and hydrological properties using pedotransfer functions can support various applications. This includes the development of the planned Operational Drought and Water Scarcity Management System, the foundation of irrigation development investments, the implementation of natural water retention measures, groundwater resource modelling, agricultural water management policy programmes.

Acknowledgement: The work was carried out within the framework of the Széchenyi Plan Plus program with the support of the RRF 2.3.1 21 2022 00008 project and the Sustainable Development and Technologies National Programme of the Hungarian Academy of Sciences (FFT NP FTA).

Recent droughts have had a significant impact on soils around the world. Tunisia, in particular, has experienced drought and human-induced soil salinisation.

The Harmonized World Soil Databases were the only global source of soil data specifically for soil salinity assessment. Recently, advances in Remote sensing have been made in measuring different soil salinity indices on agricultural land using machine learning approaches.

In this study, we aimed to investigate the spatio-temporal variability of soil salinity of an agricultural area in northern Tunisia, which is composed of Quaternary sediments, utilized for the cultivation of artichokes, cereals, and pears by using of the Google Earth Engine (GEE) platform.

Landsat series 5, 7 and 8 images from 2000 to 2023 were used, (i) soil salinity indices,

(ii) ground points (GPs), (iii) laboratory analysis was used to prepare the training data that served as input for the construction and execution of the code.

Surveys were conducted in irrigate soils, formed on alluvium of the Medjerda river. Resulting in the collection of twenty samples, specifically from the soil surface (0–20 cm).

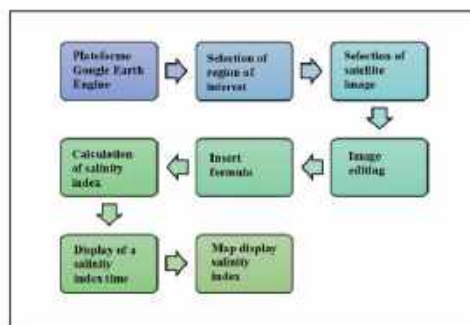

Results revealed a range of electrical conductivity of saturated paste, varying from 1.17 dS/m to 5.90 dS/m, pH levels ranging from 7.12 to 7.45.

Utilising the GEE platform, the salinity indices initially registered a value of 0.2 for the area in 2005, increased to 0.30 in 2010 and in 2023 this value surpasses 0.29.

The use of the GEE platform made it possible to process large amounts of data to generate specific products, the results of which show an increase in areas with a very high probability of saline soils occurring between 2005 and 2023.

Soil salinity is known to increase primarily due to intensive irrigation practices, affecting both pH and soil salinity. Additionally, improper drain management disturb soil chemical properties, structures, and water quality.

Based on the study's findings, it is suggested that salinization frequency is likely to increase in the near future.

#### PHOSPHORUS TRANSPORT BY SOIL EROSION IN THE ELBE BASIN

B. JACHYMOVA, J. KRASA, J. DEVATY, L. STROUHAL, A. BABULJAK, M. BAUER, T. DOSTAL

CTU in Prague, Faculty of Civil Engineering, Prague, CZECH REPUBLIC

Soil erosion is a natural process that is associated with the occurrence of intense rainfall-runoff events. As a result of climate change, the frequency of these intense rainfall-runoff and erosion events is increasing in the conditions of the Czech Republic. The consequences are manifested in many areas (soil quality, municipal infrastructure, etc.). One of the most significant areas is quality of surface water sources, which are burdened by sediment input from agricultural land, which is often enriched by large amount of bound nutrients. In conditions of the Czech Republic, the phosphorus is the limiting element that most often determines the development of water eutrophication due to an increased concentration of nutrients.

Despite the fact the most important source of phosphorus in water is usually point sources, the soil erosion is also an important source of surface water pollution (sediment and erosion-related phosphorus). In order to be able to effectively design measures to reduce the phosphorus input into surface waters in the Elbe basin, a comprehensive analysis of the entire basin was carried out. Presented analysis was focused on defining the main sources of phosphorus in individual parts of the hydrographic network.

The article presents an erosion analysis in the Elbe basin carried out using the WaTEM/SEDEM erosion model. For the analysis, mostly generally available data were used, which, due to their detail, make it possible to define the main sources of erosion material and erosion-related phosphorus for surface water bodies in the Elbe basin.

The article presents the main data sources and the methodology of processing a large area. Furthermore, the main results of the study are presented, which is the division of the area under consideration into sub-basins, for which produced amount of eroded material and erosional phosphorus is defined in the form of specific values and the degree of significance of these localities in relation to the watercourse network.

#### SAMPLING DESIGN FOR MACHINE LEARNING PREDICTIONS OPTIMIZED FOR OBSERVATION TYPES WITH DIFFERENT MEASUREMENT ERRORS UNDER A GIVEN BUDGET

M. NUSSBAUM <sup>1</sup>, S. OECHSLIN <sup>2</sup>, S. BURGOS <sup>2</sup>, S. TANNER <sup>2</sup>

<sup>2</sup> Bern University of Applied Sciences (BFH), School for Agricultural, Forest and Food Sciences (HAFL), Zollikofen, SWITZERLAND

High-resolution space-time soil information has recently gained large importance for policy makers and many other stakeholders. To provide the needed level of detail new sampling campaigns are needed, but are often under very restricted budget. Optimal selection of locations and sample tools becomes therefore crucial.

Traditionally, the positioning of new samples has been extensively explored within classical geostatistics and optimization strategies are available for kriging methods. However, contemporary mapping mostly relies on machine learning (ML) model prediction. In addition, proxy-technologies evolved fast over the past years providing sensors for quicker property measurement at lower cost, but with larger measurement errors or providing indirect measurements only. Consequently, observations vary, ranging from expensive wet-chemistry or laboratory spectroscopy measurements over less accurate field spectroscopy or field expert estimations and may even include observations from citizen science initiatives.

In a simulation study, we explored the impact of various budget allocation scenarios on the predictive accuracy of machine learning-generated soil property maps. Scenarios spanned from utilizing a small number of costly samples with minimal measurement error to a large number of low-cost samples. Measurement errors were introduced through random disturbance and model performance was assessed across multiple soil properties. Our findings underscore the significance of thoughtfully balancing diverse sampling tools within budget constraints.

Declining productive capabilities of land and their rapid transformation into a degraded state is emerging as a major concern of scientists and farmers across the globe. Several researches have identified lacunae in management of soil, land, water and crop plants at micro level as the core reasons. Deterioration of resource capabilities starts at the farm level due to nonavailability of site specific management strategies farmed as per potentials and limitations of soil and land. To mitigate this fundamental issue a decision support system (DSS) was evolved on the bases of site specific characters of soil and land through land resources inventory (LRI) on a map of 1:7920 for 229 micro watersheds (1.5 lakh ha) in Bidar district, Karnataka state, India. Soil properties such as texture, depth, pH, EC, status of major secondary and micro nutrients along with the physical features of land comprising of slope, erosion status were characterized. Site specific recommendations for crop suitability, nutrient management, soil and water conservation measures were developed. To build a DSS in the form of LRI cards at farm level and atlas at micro watershed level (MWS), field and laboratory attributes were processed through GIS to generation of thematic maps. Further for planning, implementing and monitoring purposes a digital portal was developed. Ballur-2 MWS (622 ha), one among 229 was chosen as a case study to illustrate deployment of DSS at farm and MWS level. Out of total area, land parcels suffering from limitations such as very shallow soil depth (7.5%), moderate to severe erosion (44.16%), deficiency of available N (69.05%), P (100%), Zn (100%) were identified. Appropriate crops along with suitable interventions to address identified problems for respective site were recommended through LRI card and atlas at MWS level. Similar DSS can be developed for effective management of resources to ensure sustainable productivity by restoring and conserving capabilities of soil, water, land and crops in different geographies of the world.

#### PREDICTING AND MAPPING SOIL ORGANIC CARBON (SOC) STOCKS IN AGRICULTURAL TOP SOIL IN POLAND USING QRF ALGORITHM AND LARGE DATABASE

S. PINDRAL <sup>1</sup>, J. COBLINSKI <sup>2</sup>, N. SABY <sup>2</sup>, A. KLIMKOWICZ-PAWLAS <sup>1</sup>, J. NIEDZWIECKI <sup>1</sup>, G. SIEBIELEC <sup>1</sup>, B. SMRE CZAK <sup>1</sup>

<sup>1</sup> Institute of Soil Science and Plant Cultivation - State Research Institute, Pulawy, POLAND

<sup>2</sup> INRAE, Info&Soils, Orléans, FRANCE

Soil organic carbon (SOC) is a key indicator influencing soil quality and fertility. Predictive maps of the SOC-linked indicators are crucial to meet the assumptions of the Proposal for a Directive on Soil Monitoring and Resilience and to prepare national policies and soil protection plans. In Poland, more than half of the soils' area under agricultural use has a relatively low clay fraction share and low pH. Therefore, the substantial increase of SOC stocks for the next decades appears as a challenge for Polish agriculture. The study aims to estimate the spatial distribution of the SOC stocks for agricultural top soils in Poland. To achieve this goal, we combine spatial estimates of the soil parameters to compute SOC stocks. The SOC content and bulk density estimates were based on DSM approach based on an extended national databases. For mineral soils, we used a dataset from 2018 ( $n > 40000$ ) measured for 0-20 cm, for organic soils the dataset from 2022 ( $n > 5000$ ) measured for 0-30 cm. To create prediction maps we used Digital Soil Mapping (DSM) approach and Quantile Regression Forests (QRF) algorithm. We run four independent models: for SOC content and bulk density, each divided into mineral and organic soils. The cross-validation results show relatively good modelling performance for SOC content, where  $R^2=0.32$ ,  $RMSE=1.71$  for mineral soils and  $R^2=0.35$ ,  $RMSE=20.09$  for organic soils. For bulk density, the cross-validation results were  $R^2=0.18$ ,  $RMSE=0.53$  for mineral soils and  $R^2=0.33$ ,  $RMSE=0.22$  for organic soils. Our findings show that mean SOC stocks were  $521 \text{ t}\cdot\text{ha}^{-1}$  for organic soils and  $50 \text{ t}\cdot\text{ha}^{-1}$  for mineral soils. However, it should be noticed that the decrease in bulk density and at the same time lower values of this parameter underestimates SOC stocks. Based on these findings, further research needs to implement the correction equation for better and more accurate SOC stocks calculations. It is crucial to provide high-quality maps supporting further national policies, carbon farming, and soil protection goals.

#### CHALLENGES, STRENGTHS AND WEAKNESSES OF DIFFERENT BASELINE OPTIONS FOR MONITORING SOIL CARBON REMOVALS – INSIGHTS FROM THE MARVIC PROJECT

G. RUYSSCHAERT <sup>1</sup>, L. LORAND <sup>2</sup>, H. XU <sup>1</sup>, E. LANCKRIET <sup>2</sup>

<sup>1</sup> Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Merelbeke, BELGIUM

<sup>2</sup> AGROSOLUTIONS Consulting, Paris, FRANCE

For reaching the EU ambition of climate neutrality by 2050, drastic greenhouse gas emission reductions are needed as well as carbon removals. Carbon farming captures CO<sub>2</sub> from the atmosphere and stores carbon in soils and standing vegetation. Land managers get more and more interested as most carbon farming practices deliver also soil based co-benefits such as resilience against weather extremes and positive impacts on biodiversity. Through carbon farming schemes, land managers can get rewarded for their positive contribution to societal challenges by issuing carbon certificates. In recent years, carbon farming schemes are rapidly expanding. Through the Carbon Removal Certification Framework (CRCF), the European Commission wants to set out criteria for high-quality carbon removal certificates (QU.A.L.I.TY criteria) and rules for monitoring, reporting and verification (MRV). MARVIC is a Soil Mission project that supports the CRCF and aims to develop a framework for the design of harmonized, context-specific MRV systems for carbon farming in arable land, grasslands, agroforestry/woody crops and managed peatlands. It is investigated how different building blocks of benchmark sites, sampling schemes, data layers, farm data, remote sensing and modeling can be smartly assembled to develop robust scalable monitoring systems. In addition, different options for the QU.A.L.I.TY criteria are investigated. Here, we focus on different options to calculate baselines. Two broad categories are standardized (regional) baselines or project-specific baselines. In MARVIC we have identified more than 15 different options, depending e.g., if based on soil organic stock measuring/remeasuring or modeling and ex-ante or ex-post calculations of baselines. For baseline calculations based on modeling, hybrid approaches could exist in which some input parameters are determined ex-ante and others would better be re-determined ex-post, e.g. for also capturing weather extremes in the baseline. The pros and cons of baseline options are assessed against a set of criteria such as cost (allocations), data requirements, scalability and risks and opportunities for farmers, in order to facilitate choices to be made at the policy level.

**MACHINE LEARNING MODELS FOR PEDOTRANSFER FUNCTIONS AND AN INSIGHT INTO TRANSFERABILITY: USE OF OPEN ACCESS LUCAS 2015 DATA IN THE MEDITERRANEAN BIOGEOGRAPHIC REGION FOR PH AND CaCO<sub>3</sub>**

F. KAYA, L. BASAYIGIT

Department of Soil Science and Plant Nutrition, Faculty of Agriculture, Isparta University of Applied Sciences, ISPARTA, TURKEY

Mediterranean biogeography is primarily characterized by alkaline pH level and larger presence of CaCO<sub>3</sub> equivalent. These features are greatly influenced by climate, which is one of the key elements in soil formation. Machine learning (ML) algorithms are extensively employed for predicting soil properties by utilizing digital covariates of soil formation factors. Moreover, ML algorithms can be employed to forecast and enlighten soil processes related to pH-H<sub>2</sub>O and CaCO<sub>3</sub> in Mediterranean biogeography, hence enhancing scientific understanding of soil in similar regions. The open-access LUCAS 2015 data was used to get the pH-H<sub>2</sub>O and CaCO<sub>3</sub> analysis values of 5,755 coordinated points, as well as the values of 19 bioclimatic and 3 topographic variables of these points. Machine learning models for pH-H<sub>2</sub>O and CaCO<sub>3</sub> prediction were built using Random forest (RF), Support vector regression (SVR), and Stepwise multiple linear regression (SMLR). While building the models, 70% of the data set was utilized for training, while 30% was kept aside for testing. The deployed models were transferred to southwestern Türkiye, where typical Mediterranean biogeography, and were assessed using 91 observations. When 30% of the LUCAS data set was used for validation, the RF model had the highest performance Lin's concordance correlation coefficient (LCCC) values of 0.59 for CaCO<sub>3</sub> and 0.78 for pH-H<sub>2</sub>O. As a result of the evaluation of the transferred models with 91 observations, the SVR model had the highest performance Root mean square error (RMSE) values of 87.91 g kg<sup>-1</sup> for CaCO<sub>3</sub> and 0.52 for pH-H<sub>2</sub>O. Mediterranean region which can be attributed to the typical characteristic, the most relevant environmental predictor for CaCO<sub>3</sub> and pH prediction was the BIO-19-Precipitation of Coldest Quarter variable. Comparative results are required for the modeling and transfer processes of various mathematically based algorithms in Mediterranean biogeography, as demonstrated by the results.

#### Abstract

Soil Electrical conductivity (EC) is a proxy of soil salinity and other soil characteristics, whose monitoring is much needed in the context of climate change, increasing irrigation in agricultural areas and sea level rise. The LUCAS soil monitoring network, established in 2009, provided EC1:5 in the topsoil (0-20 cm) in the surveys of 2015 and 2018. In this work, we provide a new pedotransfer function to convert EC1:5 to E<sub>Ce</sub> using the LUCAS soil texture and soil organic carbon, and a framework for E<sub>Ce</sub> mapping with a machine-learning algorithm named Quantile Regression Forest. The results are presented as predicted E<sub>Ce</sub> in the topsoil. Among these issues, secondary salinity, limited drainage, and high load of animals stand out. Hotspot analysis per country (NUTO) revealed high topsoil E<sub>Ce</sub> levels occurred in Spain 0.187% and 0.001% in Italy of their territories respectively. Increasing E<sub>Ce</sub> can lead to constrained crop productivity. With this assessment, we try to determine the hotspots for future monitoring and understanding the main drivers for sustainable soil management in light of the new European proposal for a soil monitoring directive. The E<sub>Ce</sub> map and dataset will be made available after the peer-review publication through the European Soil Data Centre (ESDAC) and the European Soil Observatory (EUSO) dashboard.

<sup>4</sup> Freelance agronomist and pedologist, Trento, ITALY

Recent advances in remote sensing and geographic information led the way for the development of aerial hyperspectral and satellite multispectral sensors. The kiwi is a recent crop in Italy, but it has reached an agronomically important share of the market, which has been put at risk by the outbreak of the disease. The factors triggering the kiwi death are unknown. This is a syndrome difficult to resolve, whose causes are not yet been identified, although it is associated with different factors: fungi and bacteria in the roots, inappropriate irrigation practices, soil, with temperature anomalies and soil composition that seem to be a constant. Italy is one of the top producers in the world. The death in twelve years has affected ab. 8,000 hectares of plants, with a graduate reduction of the cultivated surface throughout Northern and Central Italy, with an estimated loss of ab. € 750 million gross saleable production. Aim of this experimental study is to analyse and compare the results achieved using aerial hyperspectral images, acquired within the Horizon Europe USAGE project (Urban Data Space for Green Deal), and multispectral images from Sentinel 2 and Landsat 8/9 satellites. All this, for monitoring of the kiwi's leaf system, one of the first signs of the plant's death. Further analyses are being carried out on the field, with chemical, physical and biological data to be correlated in a multidisciplinary work to highlight possible factors.

#### EVALUATING THE PERFORMANCE OF PREDICTIVE MODEL WITH DIFFERENT SAMPLING ALGORITHMS AND CALIBRATION/VALIDATION SIZES FOR MAPPING SOIL ORGANIC CARBON

Y. GAROSI<sup>1</sup>, M. MÖLLER<sup>1</sup>, M. NUSSBAUM<sup>2</sup>

<sup>1</sup> Julius Kühn Institute (JKI) -- Federal Research Centre for Cultivated Plants, Institute for Crop and Soil Science, Braunschweig, GERMANY

<sup>2</sup> Geo-Environmental Data Science - Department of Physical Geography- Utrecht University, Utrecht, THE NETHERLANDS

Using digital soil mapping techniques to predict real-spatial variability of soil properties depends on the strategy to capture soil samples and the size of calibration and validation data sets for training and validation of the model. For this purpose, we applied three sampling algorithms with four balance thresholds including 50:50%, 60:40%, 70:30%, and 80:20% for splitting of calibration and validation sets, respectively. In addition, each sampling design and size combination was tested for 50 iterations. The sampling algorithms were simple random sampling (SRS), feature space coverage sampling (FSCS), and conditioned Latin hypercube sampling (CLHS). The random forest model was used to create a statistical relationship between soil sample (dependent variable) and environmental covariates including terrain attributes and remote sensing data (independent variables). After determining the best calibration and validation size for each sampling algorithm, the best repetition number was selected for mapping soil organic carbon with uncertainty using the bootstrap technique.

**Keywords:** Digital soil mapping, Random forest, environmental covariates, bootstrap technique

#### A GEOSPATIAL PLATFORM FOR HARMONIZING AGRICULTURAL LONG-TERM EXPERIMENTS DATA ACROSS EUROPE

C. DÖNMEZ <sup>1</sup>, C. HOFFMANN <sup>1</sup>, N. SVOBODA <sup>1</sup>, T. D'HOSE <sup>2</sup>, X. SPECKA <sup>1</sup>, K. HELMING <sup>1</sup>

<sup>1</sup> Leibniz Centre for Agricultural Landscape Research, Müncheberg, GERMANY

<sup>2</sup> Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Melle, BELGIUM

Agricultural Long-Term Field Experiments (LTEs) are agricultural infrastructures for studying the long-term effects of different management practices, soil and crop properties in changing climate conditions. With durations ranging from 20 to over 100 years, these experiments offer a rich scientific legacy. Despite their significance, accessing LTE-related information has been challenging due to its dispersed nature since they are run by different universities and research institutions. To close this gap, we developed a geospatial data infrastructure, including an LTE overview map (<https://lte.bonares.de>) to compile and analyze the meta-information of the LTEs across Europe. This map consolidates and analyzes metadata from LTEs across Europe, contributing to the broader objectives of (inter)national soil-based information systems and harmonizing complex data. In collaboration with the BonaRes ([www.bonares.de](http://www.bonares.de)) and EJP Soil projects, the spatial representation of LTE locations and details derived from literature reviews and personal communication with LTE holders aligns with the aim of exposing and exchanging standardized soil information (Donmez et al., 2022; Donmez et al. 2023; Blanchy et al., 2023). By applying a threshold filter with a minimum duration of 20 years, we identified and included over 570 LTEs, offering a wealth of data pertinent to soil research, policy formulation, and decision-making. Our presentation of dispersed LTE information through the LTE overview map aims to contribute to the collaborative development of (inter)national soil information systems. This effort underscores the significance of LTEs and supports the growing interest in standardized soil information as a foundation for informed soil research, policy development, and decision-making processes.

#### ENABLING ENVIRONMENTS FOR SOIL INFORMATION SYSTEM (SIS) SUCCESS: NEW EVIDENCE FOR IMPROVING SIS INTERVENTION DESIGN

M. COLEY <sup>1</sup>, M. PARR <sup>1</sup>, S. TATGE <sup>1</sup>, F. VAN EGMOND <sup>2</sup>, M. ALLAN <sup>1</sup>, T. VAN DER WOUDE <sup>2</sup>, P. BODEVIN <sup>1</sup>, J. LEENAARS <sup>2</sup>, R. ARASAH <sup>1</sup>

<sup>1</sup> CAB International, Data Policy & Practice, Wallingford, UNITED KINGDOM

<sup>2</sup> ISRIC - World Soil Information, Wageningen, THE NETHERLANDS

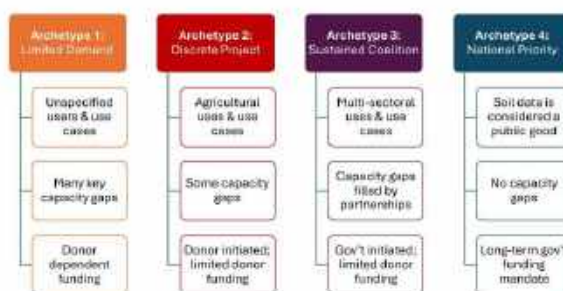

Many soil information systems (SISs) have been developed across Africa and globally to produce, organize, and serve soil information. These systems have created benefits for soil data stakeholders, yet many countries struggle to develop SISs to their full potential and to meet the needs of their intended users. What factors contribute to these challenges? How can they be addressed to fully leverage the investments in SISs in Africa?

This work, part of A Process Toward Strengthening National Soil Information Services led by CABI, supported by ISRIC and funded by the Bill & Melinda Gates Foundation, analyzed SISs across nine countries. Interviews with SIS stakeholders uncovered social, financial, institutional, and political components of in-country enabling environments that are influential for SIS outcomes, both success factors and boundary conditions. Enabling environment components were then linked with the suite of technical methods, standards and tools available for every step of the soil information workflow.

Four SIS archetypes--sets of enabling components leading to specific SIS outcomes--emerged (Figure). Three components were particularly informative: articulation of users / use cases for the SIS, severity of gaps in technical expertise, and mix of funding commitments from in-country and external investors.

A SIS is a tangible output, but it is also a process in which people and institutions must collaborate, refine, and implement plans, while balancing diverse needs, resources, and agendas. Our analysis uncovered further insights on how to define SIS success, how to approach the business case for soil data development, the key role for a soil data “champion” to ensure SIS sustainability, and on matching the ambitions of the initial SIS with the realities of users. This synthesis of socio-institutional and technological factors for SIS success is informing further work on developing and testing an improved framework for SIS intervention design.

In this session we will present the findings from our integrated analysis of existing SIS and preliminary outcomes from our developing SIS intervention framework.

<sup>3</sup> Department of Agricultural Sciences, University of Sassari, Sassari, ITALY

<sup>4</sup> Centre for Sustainable Management of Soil and Landscape (SMSL), University of Sassari, Sassari, ITALY

In the Mediterranean Regions (MR) and in particular in the Near East and North Africa Mediterranean (NENA) countries, soils and landscapes are extensively degraded and the average level of soil resources health is low and already inadequate to support economic development and food security. A primary obstacle to achieving policy targets related to the Sustainable Development Goals for 2030 is the limited availability and quality of soil data and information (SDI), coupled with their underutilization in the region. Soil data are frequently old, in non-digital format, relatively poor as quantity and quality, poorly accessible, due to limitations established by data owners, and lack effective archiving, homogeneity and consistency. Therefore, as recognized by the Global Soil Partnership action plan for the NENA region, there is a compelling need to enhance the availability and accessibility of SDI and establish harmonized methodologies to create standardized soil information systems (SIS). Steps toward this objective are being taken within the PRIMA-funded SOILS4MED project, which focuses on monitoring soil health and developing SIS to promote sustainable soil management in the MR.

A key goal of the project is to design and implement country-owned standardized SIS, facilitating the effective protection, management, update, visualization, use, and controlled sharing/publication of SDI. The project starts with a comprehensive review of legacy soil data, maps, and related methods, as well as soil classification systems in partner countries. The aim is to digitize, harmonize, and make available through a SIS all legacy data provided by partner countries, including Italy, Lebanon, Spain, France, Tunisia, Greece, Egypt, Jordan, Turkey, and Morocco.

Harmonization efforts involve addressing differences in lab methods, data specifications, and soil classification systems by developing guidelines for harmonization. The ultimate goal is to make the data understandable and usable for data owners initially, with the potential for sharing among partners and the public. This collaborative effort represents a crucial preparatory step for the future realization of the Soil Atlas of the MR.

Soil characteristics are needed to evaluate soil quality, soil health and soil-based ecosystem services. While some soil databases exist at the European scale, a much larger wealth of data is present in individual European countries, allowing a more detailed soil assessment. There is thus an urgent and crucial need to combine these data at the European scale. In the frame of EJP SOIL, a survey was conducted to assess the existing soil data sources, focusing on agricultural soils. The survey will become a contribution to the European Soil Observatory which aims to collect metadata of soil databases related to all kind of land uses, including forest and urban soils. Based upon a comprehensive questionnaire, 170 soil databases were identified at local, regional and national scales. Soil parameters were divided into five groups: (1) main soil parameters according to the Global Soil Map specifications; (2) other soil chemical parameters; (3) other physical parameters; (4) other pedological parameters; and (5) soil biological features. This survey shows that while most of the main pedological and chemical parameters are included in more than 70% of the country soil databases, water content, contamination with organic pollutants, and biological parameters are the least frequently reported parameters. Such differences will have consequences when developing an EU policy on soil health as proposed under the EU soil strategy for 2023 and using the data to derive soil health indicators. Many differences in the methods used in collecting, preparing, and analysing the soils were found, thus requiring harmonization procedures and more cooperation among countries and with the EU. In addition, choosing harmonized and useful interpretation and threshold values for EU soil indicators may be challenging due to the different methods used and the wide variety of soil land-use and climate combinations influencing possible thresholds. The temporal scale of the soil databases reported is also extremely wide, starting from the '20s of the 20th century.

#### DQ-KIT WEB APP: DATA QUALITY CHECKS FOR SOIL AND AGRICULTURAL DATA IN THE BONARES REPOSITORY AND BEYOND

S. LACHMUTH <sup>1</sup>, C. HOFFMANN <sup>1</sup>, V.H. NGUYEN <sup>1</sup>, S. LESCH <sup>2</sup>, S. RICK <sup>2</sup>, T. KÜHNERT <sup>1</sup>, X. SPECKA <sup>1</sup>, N. SVOBODA <sup>1</sup>

<sup>1</sup> Leibniz Centre for Agricultural Landscape Research (ZALF e.V.), MÜNCHENBERG, GERMANY

<sup>2</sup> Senckenberg Museum of Natural History, GÖRLITZ, GERMANY

Well-curated data repositories facilitate the discovery, access, integration, and analysis of scientific data, maximizing research impacts, and ensuring the accuracy and reliability of data-driven technologies. The BonaRes Repository serves as a FAIR and open infrastructure for soil and agricultural research data publication. Next to the repository, we are currently developing DQ-Kit, an independent web application that automates comprehensive data quality assurance.

DQ-Kit addresses data authors, data reusers, and anyone who wants to evaluate and enhance the quality of their research data. It offers automated guidance on data elements that require review and confirmation. DQ-Kit checks encompass four main categories. First, it addresses formal criteria such as atomization of data, structural consistency, and other formatting issues. Second, DQ-Kit provides a summary of variables, their properties (e.g., skewness), and summary statistics (e.g., quantiles). Third, DQ-Kit allows for the exploration of relationships among variables and patterns of missingness. Lastly, we are planning to implement data plausibility checks flagging variables that contain theoretically 'impossible' values and values that seem empirically implausible based on existing knowledge. Initially, this functionality may be limited to soil data (e.g., only pH >4 plausible in German agricultural soil), where our team possesses the necessary expertise.

Importantly, the ultimate responsibility for handling the results and alerts provided by DQ-Kit lies with the data author, who has the final authority in determining their validity. Data reusers too may have different criteria when selecting datasets for specific purposes. Therefore, the concept of 'data fitness for use' is adopted, focusing on the suitability of data for specific purposes while appreciating the efforts of data authors and amplifying their impact.

Ultimately, we plan enhancing the metadata at the BonaRes Repository with DQ-Kit results. This will enable seamless quality control and facilitate the comparison of different datasets. In summary, DQ-Kit aims to ensure the integrity and reliability of scientific data available at the BonaRes Repository and beyond, supporting a wide range of research endeavours.

#### **PARTICIPATORY SOIL, LAND, CROP DATA CATALOG TO FACILITATE INFORMED DECISION-MAKING BASED ON OPEN STANDARDS AND OPEN-SOURCE SOFTWARE**

P.P.L. VAN GENUCHTEN <sup>1</sup>, F. VAN EGMOND <sup>1</sup>, G. GENOVA <sup>1</sup>, A.T. KRALIDIS <sup>2</sup>, M. FANTAPPIE <sup>3</sup>, T. VAN DER WOUDE <sup>1</sup>, B. KEMPEN <sup>1</sup>

<sup>1</sup> ISRIC - World Soil Information, WAGENINGEN, THE NETHERLANDS

<sup>2</sup> Open Source Geospatial Foundation, TORONTO, CANADA

<sup>3</sup> CREA · Research Centre for Agrobiological and Pedology, FLORENCE, ITALY

Using up-to-date and relevant soil and other environmental information is crucial for sustainable decision-making at multiple scales and actors in agriculture, land management, policy, business, and other domains. The first challenge is often finding data and assessing whether that data is applicable, of sufficient quality, usable and relevant. Although several large repositories exist (ISRIC, ESDAC, FAO, GEOSS, ZENODO, others), it is often desirable to have a targeted repository in each geography and domain that fits specific user needs. Recent examples are a metadata catalogue for soil data in Europe (EJP SOIL), a land, soil and crop data catalogue and viewer in East Africa (LSC-IS), and a repository for the results of a pan-African soil monitoring campaign including soil spectral data (Soils4Africa).

Although these repositories are tuned to local user needs, large parts of the functional requirements are similar, so the same commonly available software components can be used. This saves costs, facilitates interoperability and enables subsequent development with every additional project. Prerequisites for these benefits are the use of open-source software and open standards for metadata, data exchange, data models and ontologies.

In the scope of the three abovementioned projects, we have developed a participatory metadata workflow and data catalogue with mapviewer based on pygeometa, pycsw, mapserver and TerriaJS. This development has followed an iterative process in which feedback from end users in different stages provided improvements to the components. The development principles are easy maintenance and preventing redundancy by importing metadata elements directly from the data sources. Open standards used are the ISO19115 metadata model, and Open Geospatial Consortium (meta)data exchange standards such as WMS, WCS, WFS, CSW, and OGC API:Records. Interoperability with academia is facilitated by an OAI-PMH interface and DOI/Datacite. The storage backend is a versioned GIT system. This enables users to participate in the administration of the platform. This system's advantages are reproducibility, interoperability and stakeholder participation.

#### A PROTOCOL FOR REPORTING CARBON DIOXIDE EFFLUX UNDER EXPERIMENTAL WARMING USING CHAMBER TECHNIQUES

D. BANSAL<sup>1</sup>, G. TALUKDAR<sup>2</sup>

<sup>1</sup> Academy of Scientific and Innovative Research (AcSIR), Ghaziabad, INDIA

<sup>2</sup> Wildlife Institute of India, Post Box #18, Chandrabani, Dehradun, INDIA

The global mean air temperature has increased by 1.1-degree Celsius since the industrial revolution and is projected to rise by 1.5 °C over the next two decades. Temperature significantly influences carbon dioxide (CO<sub>2</sub>) exchange between the biosphere and the atmosphere, impacting the global carbon cycle, potentially creating positive or negative feedback on future climate. Soil respiration, the largest source of CO<sub>2</sub> efflux from the terrestrial ecosystem, is sensitive to temperature variations. Despite the recent prioritization of studying climate warming effects on soil respiration for enhanced climate projections, there is limited documentation of reporting protocols. Addressing this gap, we propose a reporting protocol for the implications of climate warming on CO<sub>2</sub> efflux. We call this the OeXMAR (Overview, Experimental warming, Methodological approach, Assessment, Results and Outcomes) protocol. The OeXMAR protocol serves dual purpose: (a) a checklist for authors monitoring soil CO<sub>2</sub> efflux, (b) introducing a standardized format for documenting and reporting findings, ensuring transparency, reproducibility and facilitating meta-analysis review. The OeXMAR protocol, comprised of five main sections and twenty-two detailed subsections, offers both mandatory and optional elements. This inclusive structure provides authors with flexibility while maintaining a robust reporting framework. To demonstrate the protocol's efficacy, we analyze its application in ten previously published research studies, showcasing its adaptability and contribution to advancing the understanding of soil science in the context of climate warming.

### HOW THE DISTANT PAST SHOULD GUIDE THE FUTURE OF SOIL STRUCTURE RESEARCH

P. HALLETT

School of Biological Sciences, University of Aberdeen, Aberdeen, UNITED KINGDOM

A long-forgotten paper by Cameron and Gallagher (1908) developed some of the earliest tools to explore soil structure formation. Their paper included possibly the first laboratory penetrometer and compression devices, and ingenious methods to measure soil shrinkage. One shrinkage device's electronic micrometer alerted users of soil contact by a 'sharp acrid taste' from electrodes placed on the tongue. Refining this work, Haines (1923) measured soil volume changes with moisture content extremely accurately in arguably the first controlled study exploring biological polymer (gelatine) impacts to soil. He concluded that 'By means of the method the effect of alternate wetting and drying of soil in producing good tilth is illustrated.' Haines (1925) went on to derive the initial theories of capillary cohesion in soils.

This early work explored fundamental processes driving soil structure formation and stabilisation, but more recent research on soil structure has become hung up on measuring soil aggregate stability, or visualising 3D soil structure with non-invasive imaging like X-Ray CT (Fig.1). Looking back at the pioneering soil aggregate stability research by Yoder and Hénin in the 1930s, however, it went beyond collecting aggregates on sieves to measure their properties, to trying to unravel underpinning mechanisms. Researchers like Monnier (1965) built on this research to demonstrate how contact angle and particle cohesion drove the stability of soil aggregates under different management practices. Indeed, Le Bissonais's comprehensive aggregate stability test simulates different hydrological and mechanical stresses that can disrupt soil structure.

It is time for soil structure researchers to get back to basics, following the ingenuity and inquisitiveness of overlooked papers of their predecessors. With more effort placed on HOW soil structure forms, and less effort on correlating WHAT we see with the properties of soil aggregates, progress would be less incremental. We have an array of exciting new tools at our disposal, but these need to be used beyond visualisation and correlation.

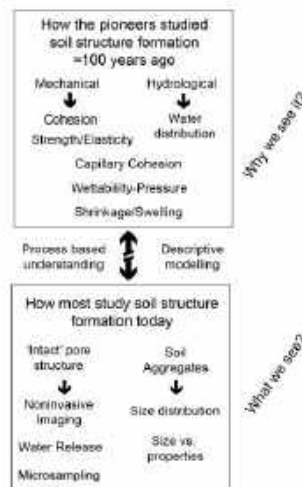

Fig. 1 - A century ago the pioneers sought WHY soil structure forms. Today we emphasise WHAT comprises soil structure. We need both.

#### DEVELOPING SYNCHROTRON TECHNIQUES TO SUPPORT AGRICULTURAL INNOVATION

E. LOMBI<sup>1</sup>, C. DOOLETTE<sup>1</sup>, E. SMITH<sup>1</sup>, P. KOPITKE<sup>2</sup>

<sup>1</sup> University of South Australia, Mawson Lakes, AUSTRALIA

<sup>2</sup> The University of Queensland, St Lucia, AUSTRALIA

#### Introduction

Synchrotron techniques were initially addressing environmental issues related to pollution. However, recent years have seen increasing interest in using synchrotron approaches for agricultural research. This presentation will focus on new methodologies using synchrotron X-ray Fluorescence Microscopy (XFM) and micro computed tomography ( $\mu$ CT). These have been developed to address some major challenges related to (i) food production, with a particular focus on fertiliser efficiency (ii) soil constraints.

#### Materials & Method

**Fertiliser efficiency:** the fertiliser use efficiency of conventional fertilisers is limited with most applied nutrients either remaining in the soil or being dispersed in the environment. However, understanding the reactions of nutrients in the fertosphere is challenging. We have developed techniques enabling us to assess distribution of nutrient availability in the fertosphere using a combination of novel large scale and robust diffusive gradients in thin-films devices (DGT) and tandem X-ray Fluorescence Microscopy (XFM).

**Soil constraints:** Crop production worldwide is often limited by one or more soil constraints such as high pH, deficiencies in macro and micronutrients, soil acidity, salinity and sodicity that limit root growth and function and crop utilisation of subsoil water. The ability of roots to grow through soil unhindered by physical or chemical constraints is key to making full use of the available water and nutrient resources. However, understanding how roots develop and respond to soil amendments is challenging. Here, we will report on the development of tomographic techniques that have enabled visualisation of roots in large soil cores from glasshouse and field trials.

#### Results

The methods developed have provided invaluable information regarding the distribution and gradients in macro and micronutrient distribution around fertiliser granules. A strong effect on availability was observed as a function of soil type and fertilisers combination. This was also related to root distribution and proliferation as a response to (phosphate fertilisers). This combination of techniques allow a thorough understanding of plant-soil relationships that can be used to enhance agronomic practices.

#### THE ANTONIO BERLESE SUMMER SCHOOL OF SOIL FAUNA TAXONOMY AND ECOLOGY

C. JACOMINI

ISPRA CN\_LAB/BIO Soil & Land Ecology Laboratory, Rome, ITALY

Soil fauna is the last frontier of soil ecology, and its complete knowledge could help determining a correct and sustainable soil management and assessment.

Recently, IUSS determined to establish a Soil Fauna Division.

Antonio Berlese (1863 - 1927) was the first soil scientist to extract edaphic fauna with a dynamic system. He was an entomologist, involved in the first successful experiments of biological pest control, who reached fame and honours studying soil fauna, producing an impressive bulk of literature.

One century after, we are proposing on his behalf a new Summer School on soil fauna, including its taxonomy, ecology and biogeography. This could be a first step to establish before his death Centennial a permanent institution on environmental high formation.

To update and increase capacity building in the field of soil ecology, we are trying to gather scientists, operational equipments from soil monitoring institutions, and graduated, Master or PhD students, in order to keep on working on this innovative and resolute field for the future decades. The aim is to continue and improve the Antonio Berlese training school, suddenly interrupted by his premature death, finally focusing on a correct identification, classification and ecological study of soil fauna.

A series of workshops, summer schools, events and biological monitoring campaigns will be promoted to increase soil zoology acknowledgment and to assess the real conditions of soils, both to promptly and effectively tackle soil degradation and to assess human impact on soils, as well as to accomplish a real-time monitoring of soil health and to support soil biological monitoring. Historical notes, practical examples and future application proposals will be discussed for a worthwhile establishment of a long period training institution, 'bringing to light the undiscovered secrets of life in soil, and to keep soil alive'.

#### FROM GLEY TO FOUGERITE VIA GREEN RUSTS, PAST, PRESENT AND FUTURE OF LAYERED DOUBLE HYDROXIDES IN SOILS

G. BOURRIÉ<sup>1</sup>, F. TROLARD<sup>1,2</sup>

<sup>1</sup> Académie d'agriculture de France, Paris, FRANCE

<sup>2</sup> Inrae, Avignon, FRANCE

Gley was described in 1905 by Vyssotskii as « always with a rather distinct greenish blue chroma », noting « some iron was undoubtedly present as protoxides [...] the fresh samples first were grayish green and later on became yellowish, » This colour criterion is incorporated in all soil classifications and in the WRB as either properties or features. The term « green rusts » was coined by Bernal in 1954 for intermediate compounds between Fe(0) and Fe(III) oxides. The structure of green rusts is derived from brucite by partial oxidation of Fe(II), the excess charge being compensated by interlayered anions. Green rusts belong to the larger group of layered double hydroxides (LDH), with both divalent and trivalent cation in octahedra. Green rusts were found in 1996 by Trolard et al. The natural green rust was homologated by the International Mineralogical Association in 2007, as fougérite. « Green rusts » should be now simply replaced by fougérite in soil classifications.

In fougérite, the divalent and trivalent cation are identical, with a possible electron transfer between them and thus an ordering of cations. Mg and other cations can substitute for Fe in the layer. Fougérite shows a definite crystallographic structure with two variants, depending on the nature of the interlayered anion, GR1 and GR2. Exchange of anions with the solution is possible, exactly as for cations in montmorillonite. The name fougérite thus characterizes the composition of the octahedral layer. In the fougérite from Fougères, the most likely anion is the hydroxyl OH<sup>-</sup>, but other anions, such as carbonate, chloride or sulphate could be present in reduced alkaline or saline conditions.

Fougérite can react with a large variety of metals, metalloids and organic pollutants (Trolard et al., 2022). It may have been much more abundant in reducing conditions in the past, including in sediments that oxidized after their deposition, such as red sandstones, and could have played a major role in the emergence of life in the Hadean ocean.

**Keywords:** Gley, Fougérite, Hydromorphy, Iron, Mineralogy

#### REAL-TIME MONITORING OF THE ION EXCHANGE PROCESS

A. FURMAN

Technion, Haifa, ISRAEL

Ion exchange is one of the most essential processes in soil science and has been studied for decades. Most studies look at the process through batch experiments, which yield adsorption isotherms. Those, in turn, can be used in flow and transport models. Very little is known about the transition phase of the exchange process.

In recent studies, we used geo-electrical methods (spectral-induced polarization, SIP) to track breakthrough ion exchange experiments. In SIP, a low-voltage electrical field (in a wide range of low frequencies) induces ionic movement, which can be related to ionic adsorption. Such experiments allow precise monitoring of the transport process, including the ion exchange, in a non-destructive, non-invasive fashion. Further, it enables monitoring processes where organic matter and non-soil porous media (e.g., activated carbon) are involved. One of the unexpected results of our experiment is the observation of an electrical transition state during the exchange process. We hypothesize that this state indicates when none of the involved ions are fully adsorbed. That is, the time that the desorbed ion already left the stern layer, while the adsorbed ion still did not reach it. While SIP is probably too coarse (spatially) to calibrate molecular dynamics for specific models, it opens a new perspective on adsorption processes.

**Keywords:** Adsorption, Geo-electrical methods

#### SOIL GEOCHEMICAL FINGERPRINTING FOR AGRI-FOOD AUTHENTICITY AND TRACEABILITY

P. ADAMO, D. AGRELLI, C. AMALFITANO, R. OFANO, L. RUGGIERO

Department of Agricultural Sciences, University of Naples Federico II, Portici, Naples, ITALY

Nowadays consumers are more aware of the issues surrounding food safety due to numerous food scandals over the last two decades. Soil is for plants the main source of mineral elements which can be transferred to agricultural products according to their bioavailability and pedoclimatic conditions. Therefore, differences in element distribution between geographic regions are reflected in agriproducts. This is why multielement fingerprinting is one of the most widely used technique to discriminate the geographical origin of food. In this work we tried to find a relation between mineral element content in cultivation soil and in a PDO tomato grown on the slopes of Somma-Vesuvius volcanic complex. The peculiar cultivation environment strongly influences quality and organoleptic properties of this tomato which due to its typicity it is a product susceptible to origin fraud.

For this study, cultivation soils and tomato fruits were collected from representative farms inside and outside the PDO cultivation area in 2021-2022 years. Soils were characterized for physical chemical properties and extracted for potentially and readily bioavailable elements (0.05 M EDTA, pH 7 and 1 M NH<sub>4</sub>NO<sub>3</sub>). A total of 22 elements (Ca, Cu, Fe, Mg, Mn, Mo, Na, Ni, P, K, Zn, Ba, Cd, Co, Cr, Cs, Rb, Sr, Dy, Gd, Nd, Sm) were determined in soils and tomatoes.

The PCA and LDA were used for geographical classification of soil and tomato samples. The results indicated a tendency to natural grouping of soil and tomato according to provenance farms. The mineral fingerprinting of soils and related tomato fruits from the farms inside the PDO area were correlated and compared to the cultivation areas outside PDO. LDA evidenced not-essential elements as predominant mineral elements of PDO soils discriminating the geographical origin of tomato fruits.

Work carried out in framework of METROFOOD-IT (NextGenerationEU, PNRR - M4C2, Investment 3.1 - IR0000033 - D.M. Prot. n.120 of 21/06/2022).

#### DESORPTION-BASED SOIL ENZYME EXTRACTION: FROM BREAKTHROUGH IN KNOWLEDGE TO HIGH-THROUGHPUT ENZYME ASSAY FOR SOIL FUNCTIONALITY

F. FORNASIER<sup>1</sup>, H. QUIQUAMPOIX<sup>2</sup>

<sup>1</sup> CREA VE, Gorizia, ITALY

<sup>2</sup> INRAE, Montpellier, FRANCE

Soil enzyme activity has long been studied both to understand biochemical properties of soil and as a simple, effective, and sensitive biosensor to evaluate both soil health, soil fertility, and soil disturbance using sieved soil in suitable buffer.

Soil enzymes were not extractable in high quantity up to nineties; moreover, the extracts were brown in color because solubilization of soil organic matter was the only way to increase extraction yield. These results lead to theory that enzymes were tightly bound to soil particles. Some twenty years ago we discovered that soil enzymes could be easily extracted and in high yield, by heteromolecular exchange by using a protein in excess. Very important, extracts were colorless, so no soil organic matter was extracted, meaning interactions of enzymes with soil components were different to what was thought at that time.

Such high-yield extraction procedure has enabled us to develop a high-throughput, very sensitive, microplate-based assay by using fluorogenic substrates. Currently, more than 30 enzyme activities, including both hydrolases and oxidases, can be quantified starting from a single soil extract obtained using just 300 mg of soil. Because one person can perform all those enzyme activities in 180 samples (once weighed) in just one day, this capability corresponds to a throughput of more than 100 times when compared to traditional assay procedures in flasks or tubes. Although ANOVA and other parametric tests allow to detect significant differences among samples whatever the number of enzyme assays being performed, multivariate statistics applied to this high-throughput enzyme assay enables also to evaluate the different importance of each biogeochemical cycle (C, N, P, S) in each specific investigation.

This assay has been used in more than 70 investigations published on peer reviewed journals. Investigations have included: laboratory experiments, large sets of environmental soil samples originating from Europe, Africa, Australia and Antarctica, marine sediments, and archaeology samples.

Selected results will be shown.

**Keywords:** enzyme extraction, high-throughput assay, soil health, soil fertility, soil monitoring

### 7. Soil sciences impact on basic knowledge 7.02 129627 - Plant-soil-microbe interactions in the rhizosphere and their potential to address global agricultural challenges

#### MICRODIALYSIS AS A TOOL TO STUDY RHIZOSPHERE DYNAMICS

E. TREVISAN<sup>1</sup>, R. TIZIANI<sup>1</sup>, S. BUCKLEY<sup>2</sup>, S. JÄMTGÅRD<sup>2</sup>, S. CESCO<sup>1</sup>, T. MIMMO<sup>1,3</sup>

<sup>1</sup> Free University of Bolzano, Faculty of Agricultural, Environmental and Food Sciences, Bolzano, ITALY

<sup>2</sup> Department of Forest Ecology and Management, Swedish University of Agricultural Sciences, Umeå, SWEDEN

<sup>3</sup> Free University of Bozen-Bolzano, Competence Centre of Plant Health, Bolzano, ITALY

Microdialysis is a non-destructive technique exploiting semipermeable membranes to measure solute flux in soil, especially at root-relevant scales. It has been employed to explore soil carbon fractions, nitrogen and phosphorus availability, and to simulate root-related processes. However, its potential to monitor root exudation and root-driven processes in the rhizosphere is unknown. We hypothesised that microdialysis could be used to monitor pH shifts, nutrient uptake and root exudation in the rhizosphere.

Barley seeds were germinated in falcon tubes containing approx. 50g of agricultural soil. The soil was kept at 60% water field capacity for the whole experiment. Four infusion pumps were equipped with 8 micro-syringes (3mL), connected to a microdialysis probe (CMA 20; 20kDa, 30×0.5mm membrane) further connected to a 1.5mL collection tube. Each day for 13 days, probes were perfused with MilliQ water at a flow rate of 1µL min<sup>-1</sup> for 23h. On day 12 the shoots were removed/cut. Microplate spectrophotometric assays were used to measure NO<sub>3</sub><sup>-</sup>, NO<sub>2</sub><sup>-</sup>, Fe<sup>2+</sup>, Fe<sup>3+</sup>, PO<sub>4</sub><sup>3-</sup>, pH, Total Organic Carbon (TOC) in the dialysate.

An increase in pH was observed between day 1 and 5, which correlated with the decrease in NO<sub>3</sub><sup>-</sup> content. Indeed, NO<sub>3</sub><sup>-</sup> root uptake is mediated by proton-nitrate symporters. These results show how rhizosphere nitrogen is almost completely utilized by barley after 5-6 days, considering the small soil volume. On the contrary, nitrite, iron, and phosphate levels did not vary significantly over time. Similarly, TOC did not vary over time until day 13 when, after removing the shoot, a significant increase in TOC was observed. However, the overall TOC concentration was too low to consider performing compound-specific analysis, such as gas or liquid chromatography-mass spectrometry.

The present study demonstrates that microdialysis can be used to monitor rhizosphere processes, i.e. nutrient uptake and pH, and more in general to answer multiple research questions in the area of rhizosphere research. However, the experimental setup need to be further optimized for monitoring root exudates.

**“HOW DO ROOTS MATTER?” – UNRAVELLING THE IMPORTANCE OF PLANT ROOTS IN SOM DYNAMICS.**

A. FAVARO, F.A. DIJKSTRA

The University of Sydney, School of Life and Environmental Science, Sydney, AUSTRALIA

Soil organic matter (SOM) decomposition is directly linked to soil CO<sub>2</sub> emissions and is one of the key processes in defining the overall magnitude of the carbon (C) fluxes between terrestrial ecosystems and the atmosphere. The addition of fresh C substrates, generally considered as the most straightforward way to increase SOM stocks, can result either in the acceleration or retardation of SOM decomposition. This change in SOM decomposition caused by fresh C inputs is referred to as the priming effect (PE). A special form of PE is the rhizosphere priming effect (RPE), which involves the activity of plant roots and associated rhizosphere microorganisms in interaction with the surrounding physical and chemical environment. While mechanistically these two phenomena greatly differ, there is a tendency in the literature to explain them by the same mechanisms and drivers, which ultimately may hamper accurate predictions of the ecosystem C balance. As suggested by previous studies, PE and RPE can be related to soil nutrient availability, and especially nitrogen (N), due to the stoichiometric coupling of C and N cycles. In this review, we highlight the drivers and mechanisms that distinguish RPE from PE and how they change with N addition. First, we discuss underlying mechanisms that govern the temporal dynamics, and overall direction and magnitude of PE and RPE and their responses to N addition. Second, we develop different scenarios for PE and RPE separately, based on whether microbes are C or N limited. We then assess how different scenarios are supported by the literature using meta-analysis. Ultimately, these findings will provide a better understanding of plant root effects on SOM dynamics and further insights into the role of N in relation to C sequestration via suppressing or enhancing PE and RPE differently.

#### SOIL ZYMOGRAPHY: A DECADE OF ENZYMATIC IMAGING IN PLANT-SOIL-MICROBE INTERACTIONS AND FUTURE PROSPECTIVE

N. BILYERA <sup>1</sup>, Y. KUZYAKOV <sup>2</sup>

<sup>1</sup> Geo-Biosphere Interactions, Department of Geosciences, University of Tuebingen, Tuebingen, GERMANY

<sup>2</sup> Department of Soil Science of Temperate Ecosystems, Department of Agricultural Soil Science, University of Goettingen, Goettingen, GERMANY

Enzymes are the main drivers of biogeochemical transformations of soil organic matter, that greatly contribute to nutrients availability in agroecosystems. Soil is a very heterogeneous and “dark” environment, that hides microbial and root life. The rapid development of soil zymography – a non-invasive technique enabling in situ imaging of potential enzyme activities in soil – allows to visualize and localize the hidden microbial and root life in soil.

We aim presenting the latest methodological advancements occurred within the decade following the pioneering use of fluorogenic substrates for visualizing enzyme activities in soil. The focus extends to the spectrum of enzyme activity imaging, zymography resolution, standardization and hotspot identification. Particularly, we emphasize the integration of zymography with other visualization methods to relate spatial distribution of enzyme activities with soil acidification, root exudation, pore distribution, nutrient and water fluxes. These combined methods elucidate plant-soil-microbial interactions not only within crop rhizospheres but also in critical agroecosystem hotspots like detritosphere and biopores.

We show the current possibilities, challenges, and the potential directions for soil enzyme imaging. Soil zymography has already applied in studying natural and agricultural ecosystems under both laboratory and field conditions, offering to scale from the entire root system down to microbial communities.

In the next decade, the spectrum of enzymes in zymography imaging will be broaden to deepen the scope of hotspot localization in agroecosystems. Furthermore, coupling of zymography with physico-chemical and microbial cell imaging, and isotope applications can facilitate unraveling the complexity of soil processes, and thus improve farming practices based on these findings. Besides, we expect that soil zymography as a simple and reliable method will be further widely used by more groups from Germany, Italy, USA, China, Sweden and other countries.

The rhizosphere bacterial community is mainly dependent on plant species and soil types. Soil nematodes may also impact rhizosphere bacteria either via top-down (bacterivores) or bottom-up (herbivores and bacterivores) regulation. However, the complex trophic control of herbivorous and bacterivorous nematodes on the rhizosphere bacterial community remains largely unexplored. In this study, we investigated the separate and combined influence of bacterivorous and herbivorous nematodes (*Poikilolaimus oxycercus* and *Pratylenchus zae*) on the abundance, diversity and activity of the rhizosphere bacterial community of Italian ryegrass (*Lolium multiflorum*), and whether root traits mediated these effects. Our results show that both bacterivorous and herbivorous nematodes altered root traits, particularly root mass density and root C:N ratio, which in turn mediated their effects on rhizosphere chemistry (e.g., pH and dissolved organic carbon), thus affecting bacterial abundance, alpha diversity, and activity. Bacterivorous nematodes had both a direct effect, which reduced bacterial abundance, and an indirect effect, which increased bacterial abundance via an increase in root mass density and root C:N ratio, resulting in a net negative overall effect. The presence of bacterivorous nematodes, either alone or in combination with herbivorous nematodes, led to different compositions of the rhizosphere bacterial community. Both root traits and rhizosphere chemistry contributed to explaining variations in community composition, with rhizosphere chemistry accounting for a larger portion of the variation, though the majority remained unexplained. We conclude that root system density and C:N ratio are key factors mediating the trophic control of bacterivorous and herbivorous nematodes on the rhizosphere bacterial community. Given the high variation in bacterial community composition and the heterogeneous nature of root systems, our results suggest the need for more detailed investigations at a finer scale to understand the effects of root traits on the rhizosphere bacterial community and the trophic interactions mediated by root traits.

#### THE INTERPLAY BETWEEN ROOT TRAITS AND THE DYNAMICS OF FE PLAQUE FORMATION AND DISSOLUTION DRIVES P AVAILABILITY FROM PLAQUE TO RICE

S. MARTINENGO, M. SCHIAVON, M. MARTIN, L. CELI, D. SAID-PULLICINO

University of Turin, Department of Agricultural, Forest and Food Sciences, Grugliasco, ITALY

Iron (Fe) plaque which normally coats rice roots has a strong affinity for phosphorus (P), with a debated effect on plant P uptake. Furthermore, plant responses to P availability shape the rhizospheric environment, possibly affecting the rates of Fe plaque formation and dissolution. The role of Fe plaque to serve as a sink or source of available P may depend on root traits, themselves influenced by P availability. However, the underlying mechanisms regulating these interactions remains unclear. In this study, we hypothesized that 1) the modification of root anatomy induced by P deficiency enhances Fe plaque deposition, and 2) this, in turn, could function as a sink or source of plant-available P, depending on the activation of plant strategies to overcome P limitation. To test these hypotheses, rice plants were hydroponically grown for 60 days under P-deficient or P-sufficient conditions, with or without Fe plaque. Root traits, rhizosphere acidification, and the rates of Fe plaque formation and dissolution were investigated and linked to differences in rice P content and growth. The increased root development promoted by P-deficient conditions led to faster and greater Fe plaque precipitation on root surfaces compared to P-sufficient conditions. However, plaque formed on P limited rice roots was promptly dissolved during plant development. This effect coincided with increased rhizosphere acidification, possibly explaining plaque dissolution. After 60 days of hydroponic cultivation, P-deficient plants showed higher P uptake in the presence of Fe plaque, whereas the opposite was observed in P-sufficient plants, where Fe plaque limited plant P uptake. We therefore concluded that the role of Fe plaque in regulating P uptake highly depends on the dynamic nature of this Fe pool that is strictly linked to P availability and regulated by plant responses to P deficiency.

#### MICROBIAL EXTRACELLULAR ELECTRON TRANSFER IN WETLAND SOIL: DRIVING COMMUNITIES TO DECREASE ARSENIC CONTAMINATION

S. ZECCHIN <sup>1</sup>, S. MARZORATI <sup>2</sup>, L. CAVALCA <sup>1</sup>

<sup>1</sup> Dipartimento di Scienze per gli Alimenti, la Nutrizione e l'Ambiente, Università degli Studi di Milano, Milano, ITALY

<sup>2</sup> Dipartimento di Scienze e Politiche Ambientali, Università degli Studi di Milano, Milano, ITALY

Microbial Extracellular Electron Transfer (MEET) is supposed to be a widespread phenomenon in the environment, although the identity and metabolic pathways of electroactive microorganisms, their distribution, their relationship with plants, and the extent to which MEET affects element cycling, remain largely unexplored. Rice farming is affected by arsenic contamination due to the low redox potential in flooded bulk soil, which promotes the microbial solubilization of arsenic from soil minerals. Since arsenic is a redox-active element, MEET is supposed to play a role in its transformation. The present work aims at filling the gap between natural MEET and engineered bioelectrochemical systems, studying in depth MEET-driven arsenic cycling in rice paddies and addressing many of the open questions concerning 1) the identity of electroactive microorganisms naturally inhabiting rice paddies, 2) the metabolic pathways involved in MEET, 3) the role of MEET in arsenic cycling in rice paddies, and 4) how we can employ these functions for applicative purposes in agriculture and in the related industry.

To pursue this aim, a microcosm experiment is being carried out where the soil conductivity of a flooded rice paddy soil affected by arsenic contamination is modulated by electroactive biochar inclusion, anodic polarization, and the presence of rice plants. The microbial activities expressed at the buried anode will be characterized by metatranscriptomic profiling and related to the circulating current and arsenic transformation in the different conditions. At the end of the experiment, anodic electroactive soil microorganisms will be enriched in order to elucidate their capacity to combine extracellular electron transfer to arsenic transformation. Combining biological, chemical and electrochemical measurements will provide a model of MEET-driven arsenic cycling in rice paddies.

This project represents an innovative approach where bioelectrochemical systems are employed to study microbial ecology aspects of MEET while addressing agronomic issues, such as arsenic contamination in rice. This project is financed by the University of Milano (Piano di Sostegno alla Ricerca PSR 2021 Linea 2– Azione A).

#### THE UNIQUE RHIZOSPHERE OF AERIAL ROOTS AND ITS ROLE IN PLANT-MICROBE INTERACTIONS

M. NAZARI

Aarhus University, Aarhus, DENMARK

This study challenges the century-old definition of the rhizosphere, proposing the existence of an aerial rhizosphere that extends beyond underground roots. This new paradigm introduces the mucilage microenvironment surrounding aerial roots as a distinct ecological niche, functioning independently of soil. This study reveals the dynamic parallels between the aerial root mucilage microenvironment and the conventional rhizosphere through a rigorous comparative analysis encompassing radial extents, components, physico-chemical properties, microbiota, and functions. The spatial similarity in radial extents (1 – 3.5 mm for the rhizosphere and 0.7 – 3 mm estimated for the aerial root mucilage microenvironment) suggests a consistent reach of plant-microbe interactions. Despite divergences in components and physico-chemical properties, both ecosystems serve as spatial niches for microbial colonization and activity. The rhizosphere and aerial root mucilage microenvironment are dynamic interfaces orchestrating complicated interactions between plants and microbial communities. Commonalities in components, including water, air, mucilage, root border cells, microorganisms, and enzymes, contribute to the establishment of microbial niches, fostering dynamic ecosystems. While the rhizosphere embodies a solid organo-mineral habitat, supporting microbial attachment and nutrient cycling, the semi-solid and biofilm-like nature of the aerial root mucilage microenvironment, with its higher saturation water content, offers a specialized niche. Diversity in bacterial communities is evident, with the rhizosphere exhibiting higher diversity and enrichment in bacteria associated with plant defense and soil organic matter mobilization. In contrast, the aerial root mucilage microenvironment is characterized by nitrogen-fixing bacteria, indicating a specialized niche with properties conducive to such microbial associations. I propose a model illustrating plant-microbe interactions within the aerial root mucilage microenvironment, elucidating processes such as microbiota formation and protection, microbial utilization of mucilage sugars, and plant uptake of biologically fixed nitrogen. By challenging conventional boundaries and providing insights into microbial dynamics, this study offers a transformative lens for understanding aboveground roots, paving the way for sustainable agricultural practices and ecosystem management.

#### MONOCULTURE VS. INTERCROPPING UNDER DROUGHT: THE FATE OF <sup>13</sup>C-LABELED RHIZODEPOSITION AND THEIR EFFECT ON THE FUNCTIONING OF SOIL MICROORGANISMS

G. ANNA <sup>1</sup>, Z. QUAN <sup>2</sup>, Z. GUO <sup>3</sup>, Y. KUZYAKOV <sup>4</sup>

<sup>1</sup> University of Kassel, Witzenhausen, GERMANY

<sup>2</sup> Jiangxi Agricultural University, Nanchang, CHINA

<sup>3</sup> South China Botanical Garden, Guangzhou, CHINA

<sup>4</sup> University of Göttingen, Göttingen, GERMANY

The plant community regulates the composition and quantity of rhizodeposition; however, due to the impact of drought on plants' functioning, allocation and fate of assimilated carbon (C) in the plant-soil-microorganisms system is changed. The present study aimed i) to trace the fate of rhizodeposits in the maize-soybean intercropping and compare it with that in monoculture under drought vs. optimal moisture conditions, ii) to reveal the differences in the rhizodeposits-C utilization by microorganisms under pulse water regime.

The greenhouse experiment was conducted from June to August 2021 using 10-year-old abandoned agricultural soil. Maize (*Zea mays*) and soybean (*Glycine max*) were grown in monoculture (4 plants per pot) or intercropping (2+2 plants) until the vegetative stage (6-8 leaves), soil moisture was kept at 60% of water holding capacity (WHC). Further, plants were divided into four treatments (each had four replicates) and labeled with <sup>15</sup>N-NO<sub>3</sub> and <sup>13</sup>C-CO<sub>2</sub>. The treatments were: i) constant wet (60% of WHC), ii) constant drought (30% of WHC), iii) wet to drought (labeling was done under 60% of WHC and soil dried till 30% of WHC and further kept for 14d), and iv) drought to wet (labeling was done under 30% of WHC and soil was slowly rewetted to 60% of WHC and further kept for 14d). Under drought, higher biomass of soybean roots was found in intercropping, whereas no effect was found in the case of maize. Drought increased NO<sub>3</sub>-concentration in soil solution and nitrification rates, and a positive impact of intercropping was seen under wet-drought. The presence of intercropping increased microbial biomass C and the contribution of both maize and soybean into <sup>13</sup>C-dissolved organic C under drought. Activities of β-glucosidase and chitinase increased under drought in intercropping, whereas acid phosphatase was suppressed. Thus, intercropping can promote the transfer of available C into the soil by altering belowground plant biomass and can help mitigate drought for the plant-soil system by improving C and N cycling.

#### UP IN THE AIR: AN AEROPONIC APPROACH TO DECIPHERING THE ROOT EXUDATE COMPOSITION DURING DROUGHT

J. HOWE, H. COKER, H. LIN, P. SMITH

Texas A&M University, College Station, USA

The composition of root exudates is known to influence nutrient availability and stimulate interactions with microorganisms. However, collection of root exudates is difficult due to potential breakage of fine root hairs causing roots to leak, sorption to soil components, and rapid decomposition by microorganisms. In addition, exudate profiles are known to vary with time and changing environmental conditions. An aeroponic method was developed to non-destructively collect root exudates from the same plants over time under various stressors (e.g., drought, nutrient deficiency, and other environmental stresses). Root exudates from mature cotton were collected throughout ideal, water-stressed, and water stress recovery. Exudates were collected every 2-3 days and characterized using a variety of techniques (e.g., FT-ICR-MS, ICP, combustion, HPLC) to evaluate root exudate composition qualitatively and quantitatively. This project is a first step in subsequent experiments to evaluate the effect of root exudates on microbiome and carbon interactions in the soil. Results indicate that water stress increased total metabolites, particularly those with nitrogen and phosphorus. Although amino acids were a small portion of exudates, drought greatly increased amino acid release. A better understanding of exudates has potential to advance science in carbon sequestration, plant breeding, and understanding plant-microbe relationships.

**LET'S INVESTIGATE THE RICE RHIZOSPHERE! LOOKING INTO THE INTERACTIONS BETWEEN BELOWGROUND C AND IRON CYCLING AND THEIR IMPLICATIONS FOR CH<sub>4</sub> EMISSIONS**

A. EHLINGER<sup>1</sup>, D. PATONO<sup>1</sup>, L. CELI<sup>1</sup>, D. SAID PULLICINO<sup>1</sup>

<sup>1</sup> Università degli Studi di Torino, Torino, ITALY

<sup>2</sup> Istituto Universitario Scuola Superiore di Pavia, Pavia, ITALY

Rice paddies are important sources of methane (CH<sub>4</sub>), but they also serve as important carbon (C) sinks. Although the effects of post-harvest residue C inputs on CH<sub>4</sub> emissions and SOC stabilization have been widely studied, the role of belowground C allocation during the rice cropping season has received less attention. Here we aim to elucidate the rhizosphere processes that link rhizodeposited C to microbial C use and interactions with Fe cycling and CH<sub>4</sub> production under anaerobic conditions. We hypothesized that an increase in rhizodeposition would (1) stimulate the reductive dissolution of Fe(III) oxides by anaerobic Fe-reducing bacteria, releasing more Fe(II) and soil-derived dissolved organic carbon (DOC) to the soil solution, particularly in soils with higher pedogenetic Fe contents; (2) enhance CH<sub>4</sub> production from both root and soil-derived C sources, the partitioning of which depends on soil properties. To test these hypotheses, a planted rice pot experiment was set up with two soils having different pedogenetic Fe contents. Rhizodeposition was modulated by applying different doses of N fertilization. Pulse-chase <sup>13</sup>C<sub>2</sub>O<sub>2</sub> labelling was used to trace plant C allocation, net C rhizodeposition, its contribution to soil and microbial C pools, and CH<sub>4</sub> emissions. From our preliminary results, the effects of root C exudation on Fe and C cycling in the rhizosphere were strongly dependent on intrinsic soil properties. Indeed, a lower reductive dissolution of Fe phases and release of Fe(II) in solution and less CH<sub>4</sub> emissions were observed in the soil with lower amounts of pedogenetic Fe. On the other hand, the different fertilization treatments, which modulated root development and possibly also gross rhizodeposition, did not show any significant effects on the dissolution of Fe(II) and CH<sub>4</sub> emissions. These results suggest that differences in soil pedogenic characteristics may play an important role in driving the effects of belowground C allocation on C cycling in rice paddies.

<sup>3</sup> Netherlands Organisation for Scientific Research, Den Haag, THE NETHERLANDS

Increasing air temperatures and precipitation can influence the carbon (C) exchange rates in arctic ecosystems. The following effect on the soil-plant carbon pools can be both positive and negative, but net effects are unclear. Here we report responses on soil-plant carbon pools after nine years (2012-2021) of increased snow depth (snow fences), summer warming (open top chambers) and the combination in a tundra ecosystem in West Greenland. Data includes characteristics of depth-specific soil samples, including the rhizosphere soil fraction, as well as vegetation responses analysed based on NDVI-derived traits, LAI and aboveground-, litter- and root biomass. Furthermore, natural vegetation growth through the study period was quantified based on time-integrated NDVI Landsat 8 satellite imagery. We concluded that warming resulted in a significant and positive vegetation response driven by *Betula nana*, while snow addition alone resulted in a significant negative response for *Betula*. Treatments had significant effects on belowground traits. The rhizosphere soil characteristics differed from those of the bulk soil regardless of treatment. For rhizosphere a significant treatment effect on soil C was noted as an increase in near-surface and top 20 cm with respect to warming, which was not observed for the bulk soil fraction. The study highlights the plant-specific response to treatment and impacts on belowground C pools likely driven mainly by dead fine roots, via *Betula nana*. We conclude that long-term warming treatment resulted in a significant and species-specific, positive plant response, and a corresponding significant increase in both above- and belowground C pools. We also conclude that changes in soil C is more clearly observed in the rhizosphere soil fraction, which should receive more attention in future assessments of SOC changes.

#### DOES ROOT PRESENCE IMPACT PESTICIDE DEGRADATION OUTCOMES?

J. NUNNS<sup>1</sup>, W. OTTEN<sup>1</sup>, M. PAWLETT<sup>1</sup>, L. SHAW<sup>2</sup>, R. OLIVER<sup>3</sup>

<sup>1</sup> Cranfield University, Cranfield, UNITED KINGDOM

<sup>2</sup> University of Reading, Reading, UNITED KINGDOM

<sup>3</sup> Syngenta, Bracknell, UNITED KINGDOM

Roots exert a significant amount of influence on the soils they inhabit. They have the potential to increase microbial biomass and cause shifts in the composition of the microbial community, due to changes in nutrient content alongside the pro- and anti-biotic nature of root exudates.

However, the influence of plant roots on pesticide biodegradation via root-mediated impacts on microbial communities is rarely considered in pesticide degradation trials. This omission is especially relevant for post-emergence pesticides where application will not occur without root presence in the soil. Roots have the potential to impact pesticide degradation through changing the prevalence of degrading bacteria and fungi, and the abundance and activity of these. Further understanding the influence of roots on biological properties and processes is needed for the development of future innovative chemicals and crop protection products.

We quantified the effect of root presence on pesticide degradation, and the response of soil microorganisms in 1.2 m<sup>2</sup> lysimeters over a period of 3 months. The lysimeters were filled with a sandy loam soil at two bulk densities (1.13 and 1.34 g/cm<sup>3</sup>), and either left unplanted or planted with spring wheat. These lysimeters were then sprayed with a fungicide and herbicide to monitor degradation rates. Soil samples were taken 0, 7, 14, 30, 60, and 90 days after spraying to quantify pesticide breakdown, and microbial response (microbial biomass, fungal biomass, community response using phospholipid fatty acid analysis, and soil surface activity and light influence using chlorophyll content).

Slower decay was observed in the planted treatment, with the herbicide half-life being 50% longer in planted treatments. Community response, fungal biomass and surface activity were found to be significantly different between the planted and unplanted treatments.

#### RELATIONSHIPS BETWEEN SOIL PROPERTIES AND MICROBIOME ASSOCIATED WITH MYCELIUM OF THREE SPECIES OF BASIDIOMYCETEA: FAIRY RINGS IN THE GARDEN OF THE ROYAL PALACE OF CASERTA (ITALY)

M ZOTTI, R DI LECCE, M IDBELLA, A ZOINA, G BONANOMI, M A RAO

Department of Agricultural Sciences, University of Naples Federico II, Portici, ITALY

In stable meadows, the biological phenomenon of fairy rings (FR) are generated by the mycelium growth of basidiomycete fungi. The mycelium expands underground colonizing new spaces outwards and, consequently, the soil becomes crumbly, whitish, and with a characteristic odour. The presence of FRs also causes a change in the vegetation on mycelium development fronts and the presence of fungal sporophores. FR are classified according to their effect on vegetation:

- Type I, they first cause suppression of vegetation at the fungal front and then a stimulation after the passage;
- Type II, they induce a stimulation of the vegetation;
- Type III, they cause no effect.

In November 2021, three FRs formed by three different basidiomycetes were observed in the gardens of the Royal Palace of Caserta. Thus, a study of their effects on the soil microbial population and chemical and biochemical properties started. Different species formed the three FRs: *Marasmius oreades* (Type I), *Amanita vittadini* (Type II), and *Clitocybe collina* (Type III). The presence of different fungal species in the same biological forms allowed comparing the effect of macro fungi on soil. For each FR the soil was sampled at three different positions in the ring and five replicates per position. Soil samples were taken in an area where no fungal passage occurred (OUT), at the fungal front (ON), and where mycelium passage occurred one meter from the fungal front (IN). The presence of the fungi led to soil acidification and an increase in electrical conductivity, linked to an increase in nutrients, as demonstrated by an increasing bioavailability for each nutrient. An increase in organic carbon, microbial biomass, and soil respiration was also observed in the presence of fungal mycelium. Based on the enzymatic activity of the laccase and Mn peroxidase, a different lignin degradation strategy arose according to the present fungal species.

#### IMPROVING NUTRIENT USE EFFICIENCY IN SOYBEAN THROUGH ROOT GROWTH PROMOTION WITH TRICHODERMA VIRIDE PRIMING

S. PAUL, A. RAKSHIT

Department of Soil Science and Agricultural Chemistry, Institute of Agricultural Sciences, Banaras Hindu University, Varanasi, Uttar Pradesh, INDIA

A significant part of soybean performance is dependent upon imbalanced soil macronutrient status besides several uncertain stresses at different growth stages. Though biological nitrogen fixation (BNF) seemed a cost-effective and environment-friendly solution for nitrogen (N) management, several reports ascertained that a considerable amount of N-fertilizer is top-dressed indicating the ineffectiveness of BNF. Besides, soybean is very sensitive to phosphorus (P) and potassium (K) nutrition. Their combined effect is even more important under field conditions. To optimize production at the field scale, a different type of cost-effective management is in dire need. *Trichoderma viride*, an opportunistic endosymbiont, is renowned for alleviating plant stress and improving plants' physiological parameters. The primary objective of this study was to facilitate root proliferation of soybeans via seed-priming with *T. viride* (strain no. BHU-2953) to improve NPK uptake under graded soil fertilization. Root lengths, plant physiological parameters, and NPK contents were determined at three different time intervals. Lignification study was carried out to visualize the effect of *T. viride* inoculation. Indole acetic acid (IAA) and 1-aminocyclopropane-1-carboxylate deaminase (ACCD) activities were determined to evaluate root growth promotion through bio-priming. Results revealed that *T. viride* enhanced IAA production and ACCD activity within treated roots. A very thick lignification pattern was observed in treated soybeans; while untreated roots showed thin vascular lignification. Higher root proliferation in bio-primed treatments was able to uptake more ( $P < 0.05$ ) N, P, and K through foraging higher soil volumes. Bio-primed plants up to 80% recommended dose were able to recover similar seed P as did by untreated soybeans with 100% recommended dose; while all bio-primed soybeans with graded doses of fertilizations showed statistically similar or even higher ( $P < 0.05$ ) seed N and K recoveries as compared to untreated plants receiving full dose of commercial fertilization. Hence, cutting synthetic fertilizer doses can save the cost of cultivation. The study can serve the purpose of low-input sustainable agriculture.

<sup>4</sup> University of Debrecen, Debrecen, HUNGARY

The impact of conventional agricultural practices on soil degradation is widely acknowledged and has now led to a very serious decline in the quality of croplands, as well as the depth, carbon content, and biological potential of topsoils. Quality of soil life constitutes a fundamental aspect of soil health, encompassing the size and diversity of the soil microbiome. Among beneficial soil microbes, mycorrhizal fungi seem to be pivotal agents connecting plant roots with the soil. Arbuscular mycorrhiza (AM) stands out as the most important form of mycorrhizal symbiosis for arable crops, renowned for its multifaceted role in facilitating plant nutrient uptake, maintaining water balance, enhancing stress resistance, regulating growth and development, as well as orchestrating the rhizosphere microbiome and improving soil structure.

It is widely recognised that conventional practices such as tilling and the intensive use of fertilisers and chemicals markedly reduce the abundance and diversity of AM fungi. However, the extent to which organic or regenerative agricultural practices can enhance the mycorrhizal potential of soils remains a subject of debate.

In recent years, we have conducted numerous field studies in Hungarian agricultural settings, examining the mycorrhizal colonisation and molecular diversity of crop plants, primarily maize, under diverse agricultural treatments. Collaborating closely with companies engaged in active agricultural practices, we have observed compelling variations in root colonisation patterns, primarily attributable to agricultural setups and soil nutrient levels.

These findings offer valuable insights into the variability of mycorrhizal potential in lowland agricultural fields in Hungary, aiding in the selection of appropriate soil biological assessment methodologies to facilitate and monitor the impact of regenerative and ecological practices on soil health. Establishing a robust methodology tailored to agricultural contexts can also facilitate the evaluation of the short- and long-term effects of mycorrhizal inoculants under field conditions.

#### REGIONAL-SCALE DETERMINING SOIL MOISTURE AND TEMPERATURE REGIMES USING JAVA NEWHALL SIMULATION MODEL

A.A. JAFARZADEH<sup>1</sup>, B. MOHAMMADHOSSEINI-SAGAYESH<sup>1</sup>, F. SHAHBAZI<sup>1</sup>, A. FARAJNIA<sup>2</sup>, H. REZAEI<sup>1</sup>

<sup>1</sup> Soil Science Department, Faculty of Agriculture, University of Tabriz, 5166616471, Tabriz, IRAN, ISLAMIC REP

<sup>2</sup> East Azerbaijan Agricultural and Natural Resources Research and Training Center., Tabriz, IRAN, ISLAMIC REP

Soil moisture and temperature regimes as diagnostic soil properties play crucial role in soil classification especially in the lowest categories i.e., soil great groups. Contrary to the past era, those can be determined by a Java Newhall simulation model using present (1992-2021) atmospheric climate records derived from 52 metrological stations. The importance of such a kind of determination clears when climate change is the major challenges by the fact that it affects agricultural purposes. East Azerbaijan Province in the north-western Iran was selected as a case study since it not just is one of the most important regions for agricultural activities, but also it was faced with climate change recently. The desiccation of Urmia Lake over the past 20 years is a strong witness for this event. Furthermore, Thiessen method was also utilized in pedoclimate zoning of the entire study area using the Mann-Kendall test approach. The findings revealed that there was an increase of ( $Z=+3.18$ ) and decrease of ( $Z=-0.56$ ) in terms of temperature and precipitation, respectively. It was finally found that the study area comprises two soil moisture regimes (Aridic and Xeric) as well as three temperature regimes (Mesic, Thermic and Frigid). Moreover, the prepared maps showed that the north-western and western area within East Azerbaijan Province have drier and hotter pedoclimate conditions than others. The highest pedoclimate area is Weak Aridic-Mesic class, while the lowest one is Dry Xeric-Frigid. Overall, the findings of present research were: I) to identify soil moisture and temperature regimes using easy-to-hand data with less consuming in time and cost; II) to facilitate determining the aforementioned diagnostic soil properties at a regional scale; III) to introduce a pathway for pedologists in recognizing different categories of soil classification and to assist soil surveying and mapping; and IV) to enhance land capability and suitability evaluation in achieving sustainable agricultural development goals.

**DO CHERNOZEMS OCCUR IN POLAND? HISTORICAL DISCUSSION AND MODERN ATTEMPTS TO CLASSIFY BLACK SOILS.**

C. KABALA, B. LABAZ

Wroclaw University of Environmental and Life Sciences, Wroclaw, POLAND

Poland is situated in Central Europe in temperate climate, humid enough to result predominance of clay-illuvial soils. The spots of soils with thick, black humus horizon are considered relict, but their origin, age and naming/classification have been continuously debated. The topsoil humus horizon in these soils typically is thinner and poorer in humus compared to Chernozems of Eastern Europe. Depending on the dominant scientific school and profiles selected for debate, these soils were called 'degraded Chernozems', 'leached Chernozems', 'meadow-forest Chernozems', or were excluded from Chernozems at all. The harmonisation of criteria and terminology, initiated by FAO Legend and continued by WRB, allowed reconsideration of their status in regional or even global context. Analysis of soil profiles that have mollic/chnic horizon in five patches revealed a regional differentiation of the morphology and properties. Soils in eastern Poland (more continental area) most commonly have thick mollic/chnic horizon, have secondary carbonates in shallow subsoil, and do not have an argic horizon. Soils in SE Poland (close to the moist mountain zone) have thin mollic, but not always chnic, have thick argic, and do not have carbonates. Soils in south-central Poland have secondary carbonates, but topsoil horizons are seriously eroded (and mixed by ploughing with subsoil), and thus often do not have chnic. In SW Poland, soils do not contain carbonates, have mollic, rarely chnic, and have poorly developed argic. And finally, soils in W Poland have thick mollic/chnic horizons, often contain carbonates, but commonly have prominent gleyic/stagnic properties. The review confirmed a large variety of 'mollic soils' in south Poland and the presence of a general climate-driven E-W gradient of 'mollic soils' in south Poland ( Haplic/Calcic Chernozems – Gleyic Chernozems/Mollic Gleysols), overlapping with an N-S gradient related to landscape and land use history (Haplic Chernozems – Argic Chernozems – Argic Phaeozems). Under the long-term weak erosion, Chernozems were transformed into Kastanozems, while in case of strong erosion - into Calcisols or Regosols.

#### REPLACING THE TWO ISRAELI SOIL CLASSIFICATION SYSTEMS WITH USDA SOIL TAXONOMY

D. ITKIN<sup>1</sup>, B. NEEDELMAN<sup>2</sup>, O. CROUVI<sup>3</sup>, A. RONEN<sup>1</sup>, G. ESHEL<sup>1</sup>

<sup>1</sup> Soil Erosion Research Station, Ministry of Agriculture & Rural Development, Rishon LeZion, ISRAEL

<sup>2</sup> Department of Environmental Science and Technology, University of Maryland, Maryland, USA

<sup>3</sup> Geological Survey of Israel, Jerusalem, ISRAEL

Seldom do countries change their soil classification system. Since the late 1950s, two different soil classification systems have been applied in Israel: one at the academy, which is more physiographically oriented, and one at the governmental ministries, which is based on 'soil associations'. The reason for having two different soil classification systems in one country stems from a historical debate between two parties with different views on soil classification and mapping. Despite decades of soil surveying and many references that explain the characteristics and spatial distribution of Israel soils, there is still no systematic protocol describing the guidelines for classifying soil taxa.

These two classification schemes are outdated, unwieldy, contradictory, nearly impossible to use for international communication, and lack reference to the anthropogenic factor of soil formation (which is intense in the eastern Mediterranean). To solve these problems, the Israeli soil classification committee has embraced the USDA Soil Taxonomy as Israel's official and sole classification system. The main reasons for choosing Soil Taxonomy were 1) improving national and international communication, 2) improving soil education, 3) relying on a broadly accepted soil classification system that is routinely reviewed and updated, 4) having a systematic protocol for soil classification, 5) considering the varied soil moisture regimes (xeric, ustic, aridic) of Israel, and 6) improving academic and public awareness of soils.

The updating of Israel's soil classification is being carried out in stages: 1) examining the two existing methods of classification and soil mapping to choose which of them is more suitable as a basis for the new classification, 2) correlating GIS polygons of the old mapping to Soil Taxonomy, 3) creating a new GIS layer consisting of approximately 800 documented soil profiles, 4) forming a new model-based soil moisture and temperature raster layer (due to lack of direct data), and 5) verifying data in the field and the lab.

ORIGIN AND EVOLUTION OF SOILS FORMED FROM NOT ORGANIC LIMNIC MATERIALS AND THEIR TAXONOMIC CLASSIFICATION

S. M. BARRAGAN MARAVILLA <sup>1</sup>, M. C. GUTIÉRREZ CASTORENA <sup>1</sup>, G. A. HERNÁNDEZ VALLECILLO <sup>1</sup>, C. A. ORTIZ SOLORIO <sup>1</sup>, C. I. HIDALGO MORENO <sup>1</sup>, D. S. FERNÁNDEZ REYNOSO <sup>1</sup>, E. V. GUTIÉRREZ CASTORENA <sup>2</sup>

<sup>1</sup> COLEGIO DE POSTGRADUADOS, POSGRADO DE EDAFOLOGÍA, TEXCOCO, MÉXICO

<sup>2</sup> UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN, FACULTAD DE AGRONOMÍA, GENERAL ESCOBEDO, MÉXICO

The Limnic Materials ML of organic origin are associated like qualifier (Limnic) to four Reference Soils Groups RSGs: Histosols, Technosols, Cryosols, and Fluvisols; however, they also have, not organic limnic materials that form soils whose origin and evolution are little studied. In the Former Lake of Texcoco, there are Clayic-Loam Limnic Materials with the presence of oolites in a volcanic origin site, where the soil formation was accelerated for influence of anthropogenic activities. To understand the origin and evolution of soils former lake, we classified 44 Soil Series with the international system soil classification 'World Reference Base for Soil Resources WRB 2022'. We found that in the former lake Texcoco the Limnic Materials occur in conditions with high salt concentration, cracks of drying, presence of volcanic ash, groundwater influence, and pastization activities and dredging which give rise to: Solonetz, Solonchaks, Fluvisols, Regosols, Phaeozems, Anthrosols and Technosols, with more of 10 qualifiers, of those who stand out: Gleyic, Sodic, Limnic, Calcaric, Vitric y Raptic; and a genetic designation from up to eight letters for each horizon, for example, 3Btqcz>beta>γ y 4Ctnzγβ<lamda>. We concluded that the former lake of Texcoco soils formed from no organic limnic materials has heterogenous morphology properties and characteristics (influenced directly by human activities), that result in a complex and diverse taxonomic classification, like so different stages of evolution in these soils.

#### COMING TO GRIPS WITH COMPLEXITY OF WORLD SOILSCAPES IN WRB SOIL CLASSIFICATION

J.S. DECKERS

KU Leuven University, HEVERLEE, BELGIUM

This paper draws from a review made of some 1000 soils from soil monolith collections at ISRIC and at KU Leuven in order to update the classification of each soil monolith to the latest version of WRB and Soil Taxonomy. This update served a.o. to identify gaps in the collections and to reveal inconsistencies in WRB2022 .

Here we focus on the aspect of systematically illustrating the Reference Soil Groups (RSG) and their qualifiers in the World Reference Base for Soil Resources (IUSS Working Group WRB, 2022), with the RSG of Ferralsols as example. We review the classification of Ferralsols and their principal qualifiers, based on an analysis of typifying soil monoliths gathered from all over the world and exhibited in ISRIC's soil museum and at the KU Leuven. Examples of fully documented monoliths, illustrating the findings are given.

Based on the analysis above an alternative list of principal qualifiers can be proposed (Table). The sequence would give first emphasis to characteristics that are not indicating an intergrade with another Soil Reference Group and end with Haplic. Differences with the present WRB 2022 sequence are illustrated in the second column.

It is concluded that the WRB system could benefit from a core set of documented occurrences of Ferralsols as illustrated here, that could then be expanded if and when new additional mappable characteristics are found and documented.

The paper concludes with a call for a web-based 'WRB Documentation Centre' for the purpose of illustrating those qualifiers that have a match in soil monoliths versus those that are missing. A call is launched to the wide soil science community for providing examples of fully-documented soil profiles. Eventually, this exercise will lead to a rationalization of the qualifier lists of WRB 2022. Keywords: Soilscales, WRB 2022, documentation Centre, soil profile data

Principal Qualifiers WRB2022	Proposed Principal Qualifier
Ferritic	Ferritic
<u>Gibbsic</u>	<u>Gibbsic</u>
Rhodic/ Xanthic	Rhodic / Xanthic
<u>Geric</u>	<u>Geric / Hypergeric / Posic</u>
Nitic	highly improbable
<u>Pretic</u>	<u>Pretic</u>
Gleyic	very rare occurrence
<u>Stagnic</u>	rare occurrence
<u>Profondihumic</u>	<u>Profondihumic</u>
<u>Mollic / Umbric</u>	<u>Mollic / Umbric</u>
<u>Acric / Lixic</u>	<u>Acric / Lixic</u>
<u>Skeletal</u>	rare occurrence
Haplic	Haplic

Table: Present and Proposed sequence of Principal qualifiers in WRB for Ferralsols

#### NAMING SOILS IN THE CONTINUUM - THE BASIC IDEA BEHIND GERMAN SOIL SYSTEMATICS

E. EBERHARDT

Bundesanstalt für Geowissenschaften und Rohstoffe, Division Groundwater and Soil, Hannover, GERMANY

Soil classification was emerging already when the ISSS was founded in 1924, and kept to be an issue of discussion ever since. One of the key problems is that soils are no discrete entities and elude sharp limitations between classes (or types). The revised German Soil Systematics, to be published in 2024, still – and even more than its earlier versions – bases on the idea that each soil type marks a center in the morphogenetic feature space. Both, transitions to theoretically each other type and deviations, are possible, without abandoning the idea of clearly assigning any soil to a single systematic unit in a hierarchy suitable also for soil mapping. The hierarchy of systematic levels allows to summarize the character of a soil as a whole in a well-graded manner that is newly based on diagnostic criteria which make use of horizon designations and depth and thickness criteria. These apply an easy-to-memorize depth threshold system. Criteria directly base on the standard profile description, without asking for an additional diagnostic horizon identification. Names for systematic units – be it typical expressions, deviations or transitions – are formed like compound nouns in German, or in the lowermost hierarchical levels by adding name elements like adjectives, so that they are intuitively understood by any speaker in their graded meaning.

#### SOIL CLASSIFICATION AND THE PHILOSOPHY OF JOHN STUART MILL

C. MONGER

New Mexico State University, Las Cruces, USA

Which attribute should be used to create soil classification taxa—color, texture, mineralogy, organic matter, base saturation, depth to bedrock, moisture regime, shrink-swell? This question is fundamental to all soil classification systems. In the 1950s the developers of Soil Taxonomy adopted John Stuart Mill's philosophy in his 1843 book "A System of Logic." In this book, the English philosopher advocated two main classification precepts:

(1) Scientific classifications are best when objects are formed into groups that produce the greater number of important statements about the group. What is meant by important? Consequential. Especially, consequential in reference to a particular goal such that the classification provides the greatest good for the greatest number.

(2) Which attribute of objects should be grouped? Those attributes that cause many other attributes. For example, "differentiating attributes" used to define a class, such as the mollic horizon, have "accessary attributes" such as natural fertility and good structure that gives rise to good infiltration and aeration.

In Soil Taxonomy, soil moisture regimes are considered to be a major attribute that causes many other attributes and, consequently, were placed high in the classification hierarchy, not only because they are important for vegetation and agriculture, but also because they have significant genesis connotations. When knowing soil moisture regimes, inferences can be made, for example, about whether a soil will have redox features, carbonates, soluble salts, mollic horizons, or O-horizons under natural conditions. Soil moisture regimes built into classification systems increases to our ability to predict how soils will be changed by climate change.

#### PRONASOLOS – THE BRAZILIAN NATIONAL SOIL PROGRAM

M.L. MENDONÇA-SANTOS<sup>1</sup>, S.M. VIDIGAL<sup>2</sup>, E. SHINZATO<sup>3</sup>, I.C. MENDES<sup>4</sup>, C.E.G.R. SCHAEFER<sup>5</sup>

<sup>1</sup> Embrapa Solos, Rio de Janeiro, BRAZIL

<sup>2</sup> Empresa de Pesquisa Agropecuária de Minas Gerais, Viçosa, BRAZIL

<sup>3</sup> Serviço Geológico do Brasil, Rio de Janeiro, BRAZIL

<sup>4</sup> Embrapa Cerrados, Brasília, BRAZIL

<sup>5</sup> Universidade Federal de Viçosa, Viçosa, BRAZIL

PronaSolos is the largest Brazilian technical-scientific program in the area of soils, whose objective is to carry out the largest pedological survey ever carried out in Brazil, as well as to perform the soil governance in Brazil. This is a Program to be performed over the next 30 years, with the following goals: i) define priority areas and the work agenda for carrying out soil surveys on geographic scales equal to 1:100,000 or more detailed; ii) carry out soil surveys and their interpretations; iii) structure and operationalise the national soil information system, with public access; iv) organise the existing soil data obtained from soil surveys; v) implement innovations in soil surveys methods and related topics. Currently, less than 5% has soil survey in a 1:1000,000 scale or bigger, as recommended in PronaSolos. The biggest part of Brazil (84%) is mapped at a scale of 1:250,000. The lack of information about soils in Brazil was already highlighted by soil experts as a crucial problem. Embrapa Soils is the leader of the Executive Committee. The first results were delivered in 2019 – the selection of the priority areas to be mapped in each State - followed by the web-technological platform of soils from Brazil launched in 2020 (<https://pronasolos.sgb.gov.br/dashboards/>), containing several maps and soil data from produced over the last 60 years. The main benefit of this platform is the availability of the collection of Brazilian soil studies and soil profiles, in a single location, from centralized and easily accessible way. In 2022 this platform was updated and a collection of Carbon Stocks Maps that gave support to FAO's Carbon Maps of the World. PronaSolos will provide soil information to the society and the results will benefit more than a dozen sectors such as agricultural insurance and credit, agroecological zoning and agricultural suitability of states and municipalities, land vulnerability to extreme events in urban and rural areas, among others.

#### GLOBAL ANDISOL DATABASE: DETERMINANTS OF CARBON CONCENTRATIONS

M. KIDA<sup>1</sup>, H. NAGANO<sup>2</sup>, H. SHIMADA<sup>3</sup>, J. FUKUMASU<sup>3</sup>, R. WAGAI<sup>3</sup>

<sup>1</sup> Soil Science Laboratory, Graduate School of Agricultural Science, Kobe University, Kobe, JAPAN

<sup>2</sup> Institute of Science and Technology, Niigata University, Niigata, JAPAN

<sup>3</sup> Institute for Agro-Environmental Sciences, National Agriculture and Food Research Organization, Tsukuba, JAPAN

While soil organic carbon (SOC) is predominantly associated with soil minerals, recent regional and global studies provide increasing evidence that reactive metals, such as organically complexed aluminum (Al) and iron (Fe) and short-range-ordered (SRO) minerals, exert stronger controls on SOC than clay content, the commonly-used parameter constraining SOC turnover in models. However, the dominant types of metal or the generality of the metal-SOC relationship remain unclear as the abundance and dominant phases of Al and Fe in soil change with soil type. Andisols, relatively young soils developed on volcanic parent materials, are found under the mean annual temperature (MAT) and precipitation (MAP) spanning approximately -2–30 °C and 60–6000 mm/y, consist largely of metastable minerals that are susceptible to the exposed environmental conditions, and thus can be viewed as an ideal soil type to examine metal-SOC relationships and direct environmental controls on them. Here, we synthesize a global Andisol database from over 2850 soil samples of 574 pedons across 34 countries. We show that organically complexed Al (pyrophosphate-extractable Al, Alp), rather than Fep or SRO minerals such as allophane (acid oxalate-extractable Al and Fe), was the most important geochemical predictor of SOC concentrations regardless of the development stage of Andisols. The variation of Alp itself was explained by pH, MAT, and wetness index (MAP minus potential evapotranspiration). Clay content had little explanatory power on SOC concentrations, while exchangeable calcium showed its importance at near-neutral pH. The Alp/Fep molar ratio increased with pH decline, indicating that organo-Al complexes prevail over organo-Fe complexes at moderately acidic pH. We further found that the SOC/Alp ratio significantly decreased with MAT, suggesting that Al-bound SOC in this form is not fully stabilized but its persistence is temperature sensitive. Overall, we show that Al phases, rather than Fe, are a better substitute for clay content as a predictor of SOC concentrations at the global scale.

#### REPEATED MANURE APPLICATION ON MAIZE YIELD, N REPLACEMENT VALUE AND CARBON FOOTPRINT IN A LONG-TERM ROTATION STUDY

B. MA<sup>1</sup>, C. LIANG<sup>2</sup>

<sup>1</sup> Agriculture and Agri-Food Canada, Ottawa Research and Development Centre, OTTAWA, CANADA

<sup>2</sup> Environment and Climate Change Canada, Pollutant Inventories and Reporting Division, Gatineau, CANADA

Systematic assessment of manure applications on maize productivity as well as their ecological services and environment benefits is critical for developing sustainable agricultural systems. A field trial has been running since 1992 testing a maize-based cereal and legume crop rotation. The experiment consists of three cropping systems: maize-soybean (MS), maize-forage legume (MF), and continuous maize monoculture (MM). Maize plots were fertilized with varying levels of nitrogen fertilizer and dairy manure during the maize phase of crop rotation. The main points of the results can be summarized as follows: The continuous maize monoculture produced the lowest grain yield, while maize in rotation with forage-legume yielded the highest. On an equivalent amount of manure organic N basis, FNRVs were, on average, 0.38 ( $\pm 0.02$ ) for SM and 0.27 ( $\pm 0.02$ ) for RM, with a wide range of 0.12 ( $\pm 0.02$ ), 0.28 ( $\pm 0.02$ ), and 0.37 ( $\pm 0.04$ ) for RM, and 0.16 ( $\pm 0.04$ ), 0.39 ( $\pm 0.03$ ), and 0.48 ( $\pm 0.04$ ) for SM under the low, intermediate, and high N response conditions, respectively. N replacement values of legume crops ranged from 40 to 120 kg ha<sup>-1</sup> for maize-soybean, and from 130 to 180 kg ha<sup>-1</sup> for maize-forage legume rotation systems. The magnitude of C footprint reduction varied with N fertilizer application rates, and maize treated with 100 kg N ha<sup>-1</sup> in MS rotation produced the greatest economic yield with relatively low GHG emissions and C footprint. Our findings suggest that increased maize yields and reduced C footprints can be achieved through appropriate N application and crop rotation with forage legumes or soybeans, and that planting canola after soybeans or wheat following canola is a viable and sustainable strategy in eastern Canada.

SPECIATION AND POSSIBLE ORIGINS OF ORGANOSULFUR COMPOUNDS IN RICE PADDY SOILS AFFECTED BY ACID MINE DRAINAGE

M. REN<sup>1</sup>, C. GUO<sup>1</sup>, J. REINFELDER<sup>2</sup>, L. ZHANG<sup>3</sup>, Z. DANG<sup>1</sup>

<sup>1</sup> School of Environment and Energy, South China University of Technology, GUANGZHOU, CHINA

<sup>2</sup> Department of Environmental Sciences, Rutgers University, New Brunswick, New Jersey, USA

<sup>3</sup> School of Chemistry and Chemical Engineering, South China University of Technology, GUANGZHOU, CHINA

Although sulfur cycling in acid mine drainage (AMD)-contaminated rice paddy soils has received much attention, the potential transformations of organosulfur compounds in such soils remain unclear. We used sulfur K-edge X-ray absorption near edge structure (XANES) spectroscopy to quantify organosulfur compounds in paddy soils from five AMD-contaminated sites and one AMD-uncontaminated reference site near the Dabaoshan sulfide mining area, South China. We also determined the sulfur stable isotope compositions of water-soluble sulfate (d34SWS), adsorbed sulfate (d34SAS), fulvic acid sulfur (d34SFAS) and humic acid sulfur (d34SHAS) in these samples. Organosulfate was the dominant functional group in humic acid sulfur (HAS) in both AMD-contaminated (46%) and AMD-uncontaminated paddy soils (42%). Thiol/organic monosulfide contributed a significantly lower proportion of HAS in AMD-contaminated paddy soils (8%) compared to AMD-uncontaminated paddy soils (21%). Within contaminated soils, the concentration of thiol/organic monosulfide was positively correlated with cation exchange capacity (CEC), moisture content (MC) and total Fe (TFE). d34SFAS ranged from -6.3‰ to 2.7‰, similar to d34SWS (-6.9‰ to 8.9‰), indicating that fulvic acid sulfur (FAS) was mainly derived from biogenic S-bearing organic compounds produced by microorganisms in the soils. d34SHAS (-11.0‰ to -1.6‰) were more negative compared to d34SWS, indicating abiotic sulfurization of organic matter was the main process in the formation of HAS. Overall, our results show that AMD irrigation influences the concentrations of soil organic sulfur species in paddy soils, potentially altering key biogeochemical processes including soil carbon sequestration and heavy metal immobilization.

#### A CONTINENTAL-SCALE STUDY OF SPodosOL PROPERTIES ACROSS NORTH AMERICA AND THEIR IMPLICATIONS FOR ORGANIC CARBON ACCUMULATION

D. SPINOLA<sup>1</sup>, D. JONES<sup>2</sup>, A. STEWART<sup>3</sup>, R. PORTES<sup>4</sup>, P. SANBORN<sup>1</sup>, D. D'AMORE<sup>5</sup>

<sup>1</sup> University of Northern British Columbia - Department of Ecosystem Science and Management, Prince George, CANADA

<sup>2</sup> Forest Service - U.S. Department of Agriculture - Pacific Northwest Research Station, Olympia, USA

<sup>3</sup> School of Environmental and Forest Sciences - University of Washington, Seattle, USA

<sup>4</sup> University of Northern British Columbia - Department of Geography, Earth, and Environmental Sciences, Prince George, CANADA

<sup>5</sup> Forest Service - U.S. Department of Agriculture - Pacific Northwest Research Station, Juneau, USA

Spodosols are predominantly found in cool, moist climates within temperate regions. These soils develop from Si-rich and sandy parent materials, resulting in nutrient-poor and acidic conditions. However, in the Coastal Temperate Rainforest of Southeast Alaska (CTR), Spodosols can form from diverse parent materials, including volcanic rocks, which is not typically observed in other regions. The CTR is characterized by a perhumid climate and dense coniferous forests, contributing to enhanced podzolization. Despite existing research highlighting the distinct properties of CTR Spodosols, including elevated soil organic carbon (SOC) and Fe oxyhydroxides, there are no quantitative comparisons across North America. This study aims to bridge this gap by comparing the properties of Spodosols from the CTR with those across North America. We hypothesize that CTR Spodosols display higher Fe-Al concentrations and clay content than their North American counterparts, fostering the formation of SOC-rich mineral horizons. This would mean that pedogenesis under the bioclimatic conditions of the CTR yields optimal mineralogical and geochemical properties for carbon sequestration. We used the Soil Characterization Database and the Pedon National Database for US and Canadian Spodosols, respectively. Analyzed soil properties including Fe and Al extractions, SOC, and clay. We selected only B horizons from well-drained Spodosols, amounting to 18k data entries. Our results show that CTR Spodosols have significantly higher mean concentrations of SOC and Fe species (Fig. 1). Pedogenic Al was higher than most other regions. Clay content was higher than in some regions but lower than in others. The SOC concentration observed for the CTR surpasses the threshold of 6% for the Humods suborder, emphasizing the SOC-rich character of these soils. Since Fe and Al oxyhydroxides are often proxies for SOC accrual and stabilization, our results demonstrate that enhanced weathering under CTR bioclimatic conditions is conducive to subsurface SOC accumulation. The next step in this study is to identify the role that climate and parent material geochemistry play in the investigated soil properties.

#### SOIL ORGANIC CARBON IN SWISS ALPINE SOILS: THE ROLE OF MICROBIAL COMMUNITY DYNAMICS

K. BRIGHT, B. DIENES, M. AEPPLI

EPFL, Lausanne, SWITZERLAND

Understanding the intricate relationship between microbial communities and Soil Organic Carbon (SOC) in Alpine soils is critical as we face the challenges of climate change. Alpine ecosystems are highly sensitive to environmental change, and within them, the interaction between microbes and SOC is key to understanding present and future carbon dynamics. Microbes play a pivotal role, directly affecting SOC's stability, decomposition, and storage. This is especially central in Alpine soils, where the total carbon storage and its dynamics are largely determined by microbial processes.

Using novel tools in biogeochemistry and microbiology, we examine the diversity and functional potential of microbes across different soil depths and landscape positions in two Alpine watersheds. By correlating these findings with key environmental factors like SOC content, moisture, pH, and soil redox state, we can uncover the main mechanisms behind SOC stabilisation. Soil redox state exerts a key control on microbial metabolic pathways and thus on organic carbon transformation processes. We are particularly interested in energetic and enzymatic limitations on microbial respiration as a function of soil redox state. This interplay between microbial communities and SOC dynamics, especially in varying soil redox conditions is thus of particular interest. Alpine watersheds offer a unique setting to study the interactions between varying water tables and soil processes, essential for understanding redox effects in high-altitude ecosystems.

This research aims to illuminate how the soil environment and its microbial inhabitants influence carbon storage in Alpine ecosystems. Ultimately, our findings highlight the crucial role that Alpine soil microbial communities play in shaping SOC dynamics and ecosystem changes in the face of ongoing climate shifts.

#### FROM SOM TO SOC: A REVISIT OF THE VAN BEMMELEN CONVERSION FACTOR

T. REN, X. LI

China Agricultural University, Beijing, CHINA

It is common to estimate soil organic carbon (SOC) content from easily measured soil organic matter (SOM) data by using the van Bemmelen conversion factor (CF) of 0.58. There is strong evidence that instead of a constant, CF changes with soil properties, soil conditions, and agronomy practices. In this study, we investigate how CF varies with soil texture, land use type, and intensity of soil disturbance. Soil samples were collected from different layers of the 0- to 100-cm profile with wide ranges of texture, vegetation type, and tillage methods from North and Northeast China. SOC content was determined with automated dry combustion method, SOM content and thermal stability was measured with thermogravimetric (TG) analysis, and the weight loss of soil minerals during TG measurement was measured with X-ray diffraction (XRD) analysis. Preliminary results showed that the CF varied considerably across the soil textures, land use types, tillage practices, and soil depths. Quantitative relationships were developed to represent the changes of CF as functions of soil particle size and SOM stability, which could be applied for obtaining accurate SOC results from SOM measurements.

##### CO-AGGREGATION OF SOIL MINERAL AND ORGANIC COLLOIDS UNDER DIFFERENT PH CONDITIONS

X. GAO, L. YUAN, J. WANG

Shenyang Agriculture University, Shenyang, CHINA

The complex interaction between soil minerals and organic matter is a key process determining organic matter stability. The soil particles interaction forces at mesoscale (1-1000 nm) are the important factors driving the quantity and stability of soil mineral- organic matter binding. However, it is not clear how mesoscopic forces regulate the chemical retention of organic matter in different media environments. In this research, the common minerals (montmorillonite, illite, kaolinite) and humic acid in black soil are divided into materials, and the mesoscopic scale co-aggregation mechanism in different electrolyte solutions and humus retention under different pH conditions were studied by modern spectroscopy and dynamic light scattering methods. The results showed that (a) there was only one critical coagulation concentration (CCC) for mixture colloids with different colloidal components in a certain kind electrolyte solution. (b) The CCCs of the mixture components aggregation were always between the CCC values of each single component in the mixture. (c) Humic acid will decrease soil particle aggregation by increasing the DLVO repulsive forces. The CCCs increase with the increasing of pH in potassium solutions and decrease in calcium solutions. Based on those results we concluded that, all the components would participate in the aggregation with equal probability, and the aggregation should be driven by the average DLVO forces of the mixture components. The pH conditions, electrolyte and mineral types together determine the soil mineral- organic matter binding mechanism. The results provide a basis for further revealing the mechanism of soil organic matter stability and the improvement of soil carbon pool function.

Mineral protection mechanisms are important in determining the response of particulate organic carbon (POC) and mineral-associated organic carbon (MAOC) to future climate change. However, the underlying mechanisms for how POC and MAOC respond to climate change is remain unclear. Here, based on a soil translocation experiment designed to simulate warming and cooling, we isolate POC and MAOC to determine their responses to temperature changes and mineral protection mechanisms. Results showed that warming translocation significantly decreased POC by an average of 10.84%, but increased MAOC by an average of 4.25%. Conversely, cooling translocation led to an average increase of 8.64% in POC and 13.48% in MAOC. Exchangeable calcium (Ca<sub>ex</sub>) had a significant positive correlation with POC and MAOC during temperature changes, and Fe/Al-(hydr)oxides had no significant correlation or a significant negative correlation with POC and MAOC. Our results showed that POC was more sensitive than MAOC to temperature changes. Ca<sub>ex</sub> mediated the stability of POC and MAOC under temperature changes, and Fe/Al-(hydr)oxides had no obvious protective effect on POC and MAOC. Our results support the role of mineral protection in the stabilization mechanism of POC and MAOC in response to climate change and are critical for understanding the consequences of global change on soil organic carbon (SOC) formation, persistence, and stabilization mechanisms.

#### SOURCES OF MINERAL-ASSOCIATED ORGANIC MATTER IN TEMPERATE FOREST SOILS MEDIATED BY MYCORRHIZAL TYPE

V. VASILICA<sup>1</sup>, C. GUIDI<sup>2</sup>, K. ABDALLA<sup>1</sup>, A. WILD<sup>1</sup>, V. KURBEL<sup>1</sup>, R. PHILLIPS<sup>3</sup>, J. PAUSCH<sup>1</sup>

Temperate forests dominated by arbuscular mycorrhizal (AM) or ectomycorrhizal (ECM) tree species are characterized by divergent soil organic matter (SOM) formation and decomposition mechanisms. However, the main sources of particulate organic matter (POM) and mineral-associated organic matter (MAOM) in these systems remain undefined – particularly the relative contributions of plants and soil microbes. We informed a Bayesian mixing model with natural abundance data of stable carbon and nitrogen (N) isotopes of SOM sources, bulk SOM, POM and MAOM, in order to estimate the relative source contribution to SOM in AM- and ECM-dominated plots in a North American temperate forest. We investigated sources of SOM in N fertilized and unfertilized forest plots and at two soil depths (0-15 cm and 15-30 cm).

In both plot types, plant material was the main source of POM (>56%), whereas MAOM was mostly derived from mycorrhizal fungi (>64%). Mycorrhizal contributions to SOM increased with depth across all treatments. Under higher N availability, direct plant contributions to SOM decreased in all soil fractions within the AM system (-4.7% on average), with a corresponding increase in mycorrhizal inputs. However, direct plant contributions increased in the POM fraction of the fertilized ECM plots compared to the unfertilized ones (+6.4% and +7.4% in top- and subsoil, respectively). Overall, the contribution of plant material to SOM was consistently higher in ECM plots, compared to AM plots, especially under increased N availability.

Our results highlight divergent trends between AM and ECM forests, especially under simulated atmospheric N deposition, and underscore a heightened contribution of mycorrhizal fungi to SOM deeper in the soil. Given the shifts in tree-mycorrhizal dominance that are occurring in many forests worldwide, our results indicate that changes in SOM dynamics can be anticipated.

The increase in extreme weather events during the last years has motivated the implantation of agricultural techniques that minimize soil disturbance. The maintenance of an undisturbed soil structure reduces soil loss due to erosion. It helps in achieving a gradual enhancement of organic matter contents and therefore increases the carbon sequestration potential of soils. In order to elucidate the real impact of management on the quality and quantity of soil organic matter (SOM), long-term field experiments are essential. In this work, SOM derived from plots maintained under a conventional tillage (CT) and plots left with natural cover vegetation (NC) since 1995 from an olive orchard located in southern Spain (Benacazón, Seville) were characterized and compared to SOM of soils derived from the tree line, treated with herbicide (TL-Herb.). The analysis was performed applying <sup>13</sup>C CP/MAS solid-state NMR spectroscopy and analytical pyrolysis (Py-GC/MS). Pyrolysis-GC/MS indicated a higher diversity of biomarkers in NC soils than in CT, whereas TL-Herb showed the lowest. NMR analysis allowed the estimation of the degree of soil humification by an indicator derived from the Alkyl C / O-alkyl C ratio. This ratio was lowest for NC as these plots were receiving constantly input of fresh litter organic matter. Our study confirms that conventional tillage and use of herbicides in olive yards is not only reducing SOM contents but also SOM diversity. These results were also supported by phospholipid fatty acid analysis, which also indicated differences among the studied plots in soil microbiome composition.

This study aims at investigating the effect of climate and time on particulate organic matter (POM) and mineral-associated organic matter (MAOM) dynamics. Two chronosequences located along a climate gradient were investigated. The driest chronosequence (ADI) consisted of four fluvial terraces, whereas the wettest one (LED) included three fluvio-glacial terraces. The age of the ADI sites (Q2, Q3, Q4 and Q5) ranged from about 125,000 to 2,000 years BP, whereas that of the LED sites (Q1, Q2, and Q3) from about 16,000 to 10,000 years BP. All sites were grasslands. Soil samples (1 profile and 2 cores per site) were collected by horizon, and each horizon sub-sampled by depth (each 5 cm). From each sample, POM and MAOM were isolated and characterized by elemental and thermal analyses.

The contribution of POM and MAOM to carbon (C) storage differs among the climo-chronosequences. In the topsoil (0-15 cm), POM represents the main pool, especially in the wettest chronosequence. The average MAOM/POM ratio is almost twice in the driest chronosequence (ca. 2.6). The concentration of organic C in MAOM and POM along the whole profile is about 2x and 3x, respectively, in LED soils compared to ADI. In both chronosequences, the MAOM/POM ratio increases with depth with an unsaturated level of MAOM.

Thermal indices show that the stability of the MAOM pool increases with soil age and depth in the driest chronosequence (ADI), whereas no significant differences were observed in the wettest (LED). For the POM fraction, no significant differences in stability were observed in both chronosequences.

In conclusion, our results show that soil age plays an essential role in forming stable MAOM, in particular in drier climatic conditions. In contrast, a wetter climate determines a higher accumulation of C in both pools, although such higher C contents are negatively correlated with their thermal stability.

#### INCREASING TEMPERATURE INFLUENCE ON SOIL ORGANIC CARBON POOLS AND ON SUGAR BEET AND SOYBEAN YIELDS: PRELIMINARY RESULTS

F. ABDELKEFI, B. GIANNETTA, G. GALLUZZI, C. ZACCONE

University of Verona, Department of Biotechnology, Verona, ITALY

Soil organic carbon (SOC) plays a fundamental role in the global carbon (C) cycle and represents a key element of soil ecosystem services. Thus, the response of agricultural soils to global warming is important when assessing C accrual potential and soil fertility in a climate change scenario.

In this research we investigate the influence of global warming on SOC pools, and on the yields of two crops, namely sugar beet (SB) and soybean (SOY). A temperature increase of  $\sim 2^{\circ}\text{C}$  was simulated using Open Top Chambers (OTCs) in a randomized complete block design field experiment. Topsoil samples (0-15 cm) were collected from all plots before and after the experiment and characterized from the physical and chemical point of view. Particulate Organic Matter (POM) and Mineral Associated Organic Matter (MAOM) were also isolated.

Data collected from sensors confirmed that soil and air temperatures inside the OTCs were higher than those outside the OTCs, both in the control and in the cultivated plots. In general, SOC in the MAOM fraction was 3-4 $\times$  higher than in POM ( $76.4\pm 2.4$  vs.  $20.2\pm 4.5\%$ ) and showed a lower C/N value (8 vs. 12) suggesting a great contribution of microbial derived SOM. Following the experiment, the MAOM/POM ratio was quite different, suggesting an influence of increasing temperature on SOC distribution between pools (work in progress).

Beside affecting SOC distribution between SOM pools, the  $2^{\circ}\text{C}$  temperature increase had also a strong impact on crop yields, with average values 3 $\times$  (SB) and 5 $\times$  (SOY) lower within the OTCs than those obtained outside the OTCs, corresponding to a loss of income of 1,000-3,000 €/ha.

#### SOIL TYPE MATTERS: INVESTIGATING THE IMPACT OF ENVIRONMENTAL DISTURBANCES ON SOIL ORGANIC CARBON STORAGE – A CASE STUDY OF WINDTHROWS IN THE TATRA MOUNTAINS (S POLAND)

L. MUSIEŁOK, M. DREWNIK, M. STOLARCZYK, W. SZYMANSKI

Jagiellonian University, Institute of Geography and Spatial Management, Krakow, POLAND

Storage of soil organic carbon (SOC) is crucial for ecosystems' overall health and functionality. SOC influences nutrient cycling, supports biodiversity, mitigates climate change, and enhances soil stability and structure. Environmental disturbances, often induced by human activity, directly and indirectly affect SOC storage. Windthrows, which are an example of such disturbances, impact both the external conditions for the formation of SOC pools, including biomass production and decomposition, and intrinsic soil transformations. However, the direction and outcomes of such disturbance on SOC storage may depend largely on soil type. Mountains, characterized by high local geodiversity and susceptibility to global changes, serve as field laboratories for analyzing the effects of environmental disturbances on SOC storage. The study aimed to assess the impact of windthrows on the storage of SOC in the context of the local diversity of soil types. The impact of tree uprooting events on SOC concentration was assessed based on 340 soil profiles of the forest zone of the Tatra Mountains classified as Podzols and Cambisols (the latter developed both from calcareous or acid rocks). More than 50% of the analyzed soils were affected by the windthrows and on average showed a slightly lower SOC content recorded in O, A, and B horizons compared to undisturbed soil profiles. However, the effects of windthrows on SOC content varied significantly depending on soil type. Podzols, which generally stored more SOC in the study area than Cambisols, also showed significantly greater SOC losses due to the impact of windthrows. The most pronounced differences in SOC content in windthrow-affected and undisturbed soils were observed in the B horizons, which indicates the loss of the most stable SOC pool (deep SOC) from Podzols.

The research was supported by funds from Polish State Forests transferred to the Tatra National Park and grants from the Priority Research Area Anthropocene and the Faculty of Geography and Geology under the Strategic Programme Excellence Initiative at Jagiellonian University.

SOIL ORGANIC MATTER TURNOVER: GLOBAL IMPLICATIONS FROM D13C AND D15N SIGNATURES

Y. KUZUYAKOV <sup>1</sup>, E. SOLDATOVA <sup>2</sup>

<sup>1</sup> Dept. of Soil Science, University of Goettingen, Goettingen, GERMANY

<sup>2</sup> Center for Isotope Biogeochemistry, X-BIO, University of Tyumen, Tyumen, RUSSIA

The residence time of carbon (C) and nitrogen (N) in soil is a fundamental parameter reflecting the rates of soil organic matter (SOM) transformation. Based on the global database of the stable isotopes of C (d13C) and N (d15N) depending on soil depth (171 profiles), we assessed SOM turnover and related them to climate, biome types and soil properties. The 13C and 15N discrimination by microbial utilization of litter and SOM, as well as d13C and d15N increase with depth, enabled to assess C and N turnover within SOM. N turnover was 2 times faster than that of C because i) repeated N recycling by microorganisms, ii) C loss as CO<sub>2</sub> and input of new C atoms, which reduces the C turnover, and iii) slower turnover of N free persistent organic compounds (e.g. lignin, suberin, cellulose) compared to N containing compounds (e.g. proteins, DNA). An increase in temperature and precipitation accelerated C and N turnover because: i) higher microbial activity and SOM decomposition rate, ii) larger soil moisture and fast diffusion, iii) downward transport of 13C-enriched organic matter (e.g. sugars, amino acids), and iii) leaching of 15N-depleted nitrates from the topsoil and losses from the whole soil profile. The temperature increase by 10 °C accelerates the C and N turnover for 40%. SOM turnover is boosted by decreasing C/N ratio because: i) SOM with a high C/N ratio originated from litter is converted to microbially-derived SOM in mineral soil characterized by a low C/N ratio; ii) litter with a low C/N ratio is decomposed faster than litter with a high C/N; iii) microbial carbon-use efficiency increases with N availability. The fastest C turnover is common under evergreen forests and the lowest under mixed and coniferous ones. Concluding, the assessment of SOM turnover by d13C and d15N approach showed two times faster N turnover compared to C, and specifics of SOM turnover depending on the biomes as well as climate conditions.

#### SUBSOILS ROLE IN THE EVALUATION OF BEECH COPPICE MANAGEMENT SUSTAINABILITY: A CASE STUDY IN APENNINE MOUNTAIN (EMILIA ROMAGNA REGION, ITALY)

G. FALSONE <sup>1</sup>, E. MAZZONI <sup>2</sup>, M. DE FEUDIS <sup>1</sup>, L. VITTORI ANTISARI <sup>1</sup>, M. DI BONITO <sup>1,3</sup>

<sup>1</sup> DISTAL, Department of Agricultural and Food Sciences, Alma Mater Studiorum University of Bologna, Bologna, ITALY

<sup>2</sup> Timesis s.r.l., San Giuliano Terme, ITALY

<sup>3</sup> ARES, School of Rural, Animal and Environmental Sciences, Nottingham Trent University, Brackenhurst campus, Southwell, UNITED KINGDOM

Soil carbon accumulation and turnover dynamics affect forest management sustainability. Because of the different mechanisms (or of their relative importance) regulating C turnover in topsoils and subsoils, a different effect of forest management is expected with time. To verify it, a chronosequence of cut beech coppice (5, 11 and 16-yrs-old compared to a 70-yrs-old site) in Apennine mountains in Emilia-Romagna region (Italy) on well-drained Dystrudepts was investigated. Soil organic C stocks and organic matter decomposition estimated by C isotopes were compared in topsoils (O and A horizons) and subsoils (Bw, AC and BC horizons).

In the 26 soil pits investigated, C stock in O horizons varied from 1.89 to 4.54 Mg ha<sup>-1</sup>, and significantly differed in the oldest and youngest sites, respectively. C stock in the first 30 cm did not differ among sites (79.4±18.3 Mg ha<sup>-1</sup>), but its value was correlated with the C stock density of subsoils ( $r=0.68$ ,  $p<0.001$ ), stressing the relevance of subsoil in C accumulation. The regressed gradient (b) and constant (k) of  $\delta^{13}C$  and the logarithm of SOC with depth were indicative of the rate and the maximum value of isotopic fractionation occurring during C turnover in the deepest horizons, respectively. b and k ranged from -2.73 to -1.76 and from -25.69 to -24.63‰, suggesting different C turnover among sites possibly regulated by: priming effect in 5-yrs-old site triggered by the accumulation of organic residues in O horizon (thick O horizon and pronounced negative b and k values); root growth promoting C input and mixing processes in-situ in 11-yrs-old site (less negative values of both b and k); accumulation of more transformed and potentially more stabilized organic compounds in 16-yrs-old site (b and k values returned to be more negative). Evidence of decreasing accumulation of few transformed organic matter, potentially leading to higher CO<sub>2</sub> soil emissions, was instead found in the 70-yrs-old coppice, questioning the sustainability of this management practice in terms of C accumulation.

**Keywords:** subsoils, C accumulation, C isotopes, forest management, sustainability

<sup>5</sup> Universidade de São Paulo, Centro de Estudos de Carbono em Agricultura Tropical, Piracicaba, BRAZIL

Integrated farming systems are recognized as agricultural production models that enhance soil carbon storage. This study aimed to evaluate the influence of the tree component on the litter dynamics and soil C and N stocks in an agrosilvopastoral system in the Brazilian Cerrado. We compared nine-years-old agrosilvopastoral system (ASP) with an arrangement of 3x2+14m, with a 24-years-old nominal pasture (NP) and a native vegetation (NV). Five treatments including three sampling points in ASP [between the eucalyptus trees (P1), in the canopy projection area (P2) and in the middle of the alley (P3)], and two areas (PN and VN) were evaluated. Litterfall production from eucalyptus were evaluated in suspended collectors while the decomposition rate was evaluated in litterbags. The assessments were carried out monthly over one year, as well as CO<sub>2</sub> fluxes. Soil samples were taken at six soil layers until 0.5m depth to evaluate bulk density, soil fertility and soil C and N stocks. The litterfall production higher in P1, with decrease during the dry season. P1 and P3 showed higher decomposition rates, with final remaining mass of 28.71 and 32.33%. CO<sub>2</sub> efflux was higher in the rainy season and showed similar pattern between P1 e NV. Regarding the soil fertility, NV showed higher values of macronutrients and base saturation, and these results can be associated to the nutrient exportation and the deficit of fertilization management in ASP and NP. Soil C and N stocks at 0-50 cm depth were higher in NV (115.4 and 11.3 Mg ha<sup>-1</sup>), followed by NP (92.4 and 8.8 Mg ha<sup>-1</sup>) and ASP (89.9 and 9.0 Mg ha<sup>-1</sup>). In the sampled points within ASP, soil C and N stocks were higher in P1, showing the influence of tree component. Our results showed that the arrangement as well as the management of eucalyptus trees in the integrated farming system influenced the dynamics of litter decomposition and soil C and N storage over time.

#### STABILIZING SOIL ORGANIC CARBON DURING WATER EROSION ON LOESS SOIL : INTERPLAY OF AGGREGATES, MICROBES AND PLANTS

N. ZHANG<sup>1</sup>, Q. LIU<sup>2</sup>, B. JANSEN<sup>1</sup>, E. CAMMERAAT<sup>1</sup>, F. DE VRIES<sup>1</sup>, K. ZONNEVELD<sup>1</sup>, C. PLATENBURG<sup>1</sup>, E. MORRIEN<sup>1</sup>

<sup>1</sup> Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Amsterdam, THE NETHERLANDS

<sup>2</sup> Soil Physics and Land Management Group, Wageningen University and Research, Wageningen, THE NETHERLANDS

Soil organic carbon (SOC) forms a crucial reservoir in the global carbon cycle, but its stability can be significantly affected by water erosion. However, how soil microbes and plants interact with the known physicochemical processes on stabilizing SOC during water erosion is still unknown. We hypothesize that microbes (including mycorrhiza) with extracellular polymeric substances and plants will enhance soil aggregate stability during water erosion. This enhancement involves forming physical-protected particulate organic matter (POM) and mineral associated organic matter (MAOM).

We set up plant-soil systems with *Trifolium pratense* and *Lolium perenne* in loess soil of a low and high SOC content. Bare soils were set as control. Additionally, in the low SOC soil, we grew plants with and without mycorrhizal inoculum. In all treatments, plants were grown for eight weeks on a slope followed by simulated rainfall. Runoff, root and soil samples were collected; microbial factors, aggregate stability and SOC fractions were measured.

Our preliminary results show that both plant presence and higher original SOC content positively contributed to aggregate stability. Opposite to our expectation, the root colonization rate by mycorrhizal fungi hyphae correlated negatively with aggregate stability. Our results show, so far, that plants and mycorrhizal fungi might have contrasting roles in soil aggregate stability, and hence requires further investigation into these factors.

#### SOIL ORGANIC MATTER STABILIZATION IS ASSOCIATED WITH FUNCTIONAL DIVERSITY OF ORGANIC MOLECULES IN A TEMPERATE CONIFEROUS FOREST

S. YANG<sup>1,2</sup>, B JANSEN<sup>3</sup>, T. .B. MEADOR<sup>1,4</sup>, S JABINSKI<sup>1,4</sup>, W DING<sup>2</sup>, V JÍLKOVÁ<sup>1</sup>

<sup>1</sup> Biology Centre of the Czech Academy of Sciences, Institute of Soil Biology and Biogeochemistry, Ceske Budejovice, CZECH REPUBLIC

<sup>2</sup> State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, CHINA

<sup>3</sup> Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Amsterdam, THE NETHERLANDS

<sup>4</sup> Department of Ecosystem Biology, Faculty of Science, University of South Bohemia, Ceske Budejovice, CZECH REPUBLIC

The effects of the inherent properties of soil organic matter (SOM) on its persistence are not fully understood. A new-emerging paradigm suggested that molecular diversity is an important factor in regulating the decomposition and stabilization of SOM. However, it is still not clear how molecular diversity is associated with SOM stabilization, especially the underlying mechanisms. We collected plant and soil samples collected from a spruce forest in the Czech Republic, and performed 210-day incubations of soil samples, followed by separating soil fractions using density fractionation. A pyrolysis-gas chromatography/mass spectrometry was performed for soil fractions and plant samples to investigate the effects of molecular diversity on SOM stabilization. Relative abundances of detected monomers were used to estimate molecular diversity according to richness, Shannon index, evenness, and functional diversity (Rao's Q entropy estimated using functional groups such as hydroxyl groups and branch chains).

We detected 179 individual compounds, which were classified into 8 groups. Results showed that free and occluded particulate organic matter (fPOM and oPOM) had higher richness than mineral-associated organic matter (MAOM), but no significant difference was found for Shannon index or evenness. For functional diversity, root and MAOM exhibited a higher functional diversity of branch-chain fatty acids, suggesting a larger proportion of microbial-derived fatty acids. Needles and MAOM had a greater diversity of compounds with hydroxyl groups, suggesting that hydroxyl fatty acids derived from needles are preferentially stabilized by associations with mineral surfaces. During the 210-day incubation, the relative abundances of compounds having similar functional groups were positively correlated for oPOM and MAOM, but not for fPOM. This suggests that functional group composition of molecules is associated with the changes in SOM during the incubation. Our findings suggest that the SOM decomposition and stabilization during the incubation are regulated by the functional diversity of SOM, especially for the diversity of compounds with the same functional groups such as hydroxyl groups.

#### SUSTAINABLE GRASSLAND MANAGEMENT FOR HEALTHY SOILS AND VICE VERSA

M ANZA <sup>1</sup>, N MANDALUNIZ <sup>1</sup>, N AGIRRE <sup>2</sup>, C GARBISU <sup>1</sup>, L EPELDE <sup>1</sup>

<sup>1</sup> NEIKER -BASQUE INSTITUTE FOR AGRICULTURAL RESEARCH AND DEVELOPMENT-, Derio, SPAIN

<sup>2</sup> LURSARE Ekosistemas, Alegria, SPAIN

Soils perform a variety of functions that are vital for the proper performance of terrestrial ecosystems. For instance, they play a crucial role in regulating water flow and storage, as well as nutrient release, serving as the primary terrestrial carbon storage, while their rich biodiversity, encompassing 59% of the planet's species, facilitates these functions. However, intensive agriculture and livestock management can impact on soil ecosystem services. Among regenerative farming practices, rotational grazing regime involves dividing pastures into smaller sections, regularly moving livestock, and maintaining high stocking rates for brief periods. This approach extends resting periods in grazing areas, allowing defoliated grasses to recover and regenerate. It enhances productivity, optimizing land and resource homogeneity.

Conducted in four extensive and commercial livestock farms in the Basque Country (northern Spain), this study aimed to assess the impact of land use disturbance on various descriptors of soil health and associated functions. The land use gradient studied included woodland, rotational grazing, overgrazing and non-permanent cropping. On at least three sites for each land use and farm, up to 46 physico-chemical and biological descriptors were measured, which were then grouped into four ecological functions. While the primary focus was to compare rotational grazing with overgrazing, forests and non-permanent crops were included as references for low and high disturbance, respectively.

Overall, forest soils showed significantly higher provision of organic matter decomposition, carbon storage and water cycle regulation functions than other land uses, especially compared to non-permanent crops. Overall, the soils under rotational grazing and those we considered to be overgrazed showed no significant differences between them. Each soil studied on the four farms has different characteristics and historical management, which makes it difficult to compare the effect of rotational grazing versus overgrazing on soil health. To do this, it would be necessary to resample the same points over time to study how each of the soils evolves over the medium to long term.

#### SHORT-RANGE-ORDERED MINERALS AS ECOZONE-SPECIFIC PROXIES TO BETTER UNDERSTAND GLOBAL SOIL ORGANIC CARBON PERSISTENCE?

H. JUNGKUNST

RPTU Kaiserslautern-Landau, Landau, GERMANY

Soil organic carbon (SOC) is protected from being completely decomposed by short-range-ordered (SRO) minerals. These SRO minerals are commonly measured as oxalate-extractable aluminum (Alox) and iron (Feox) and many studies revealed positive correlations with SOC. Uncertainties remain, however, as to whether this organo-mineral relationship is a general global one, or whether regional differences will prove too relevant to ignore at the global scale. Here, we present a synthesis of globally gathered data on Alox and Feox to test whether they can be used as proxies for SOC abundance across regions. We used the Holdridge Life Zones, which are characterized by biotemperature, precipitation, potential evapotranspiration, and elevation, to define distinct pedo-climatic regions. In total, we compiled more than 31,000 individual measurements covering all major Holdridge Life Zones. The global synthesis revealed a positive relationship between Alox, Feox and SOC across regions. However, Alox and Feox are more accurate proxies for mineral-induced SOC protection at the global scale when disaggregated into regional relationships. Apparently, the wetter the region the tighter the relationship showing both higher Alox, Feox and higher SOC values. The latter is almost independent from temperature which generally showed less influence on the organo-mineral relationship. Before incorporating this organo-mineral relationship as a proxy for SOC abundance into soil models, it needs to be diversified into regions since the importance of SRO minerals for SOC persistence varies across pedo-climatic conditions.

#### CAN ENHANCED ROCK WEATHERING CONTRIBUTE TO ORGANIC CARBON ACCRETION VIA ORGANO-METAL INTERACTION?

P. YANG<sup>1</sup>, T. KOGURE<sup>2</sup>, A. NAKAO<sup>3</sup>, R. WAGAI<sup>1</sup>

<sup>1</sup> NIAES (National Institute for Agro-Environmental Sciences), NARO, Ibaraki, JAPAN

<sup>2</sup> Department of Earth & Planetary Science, Graduate School of Science, The University of Tokyo, Tokyo, JAPAN

<sup>3</sup> Department of Life and Environmental Sciences, Kyoto Prefectural University, Kyoto, JAPAN

Enhanced rock weathering is proposed as one of the climate change mitigation methods. The alkali-earth metals (esp. Ca & Mg) released by the chemical weathering of crushed rock powder can contribute to CO<sub>2</sub> removal through carbonate precipitation or leaching. The weathering also releases other metals and metalloids (Fe, Al, Si) that have strong affinities with organic matter thereby protecting organic C (OC) via complexation, co-precipitation, and aggregation. The reactive metal release is strongly driven by the surface area of rock powder. We thus hypothesized that basalt with a smaller particle size is more efficient in OC protection in addition to CO<sub>2</sub> removal compared to larger-sized basalt. To test the hypothesis, we conducted leaching experiments of basalt-POM (potato leaves)-quartz mixtures using two sizes of basalt powders (20-38 & 106-150 micrometers). Pure basalt and the mixtures were incubated at 28 degrees Celsius and leached weekly with artificial rainwater for up to 6 months. Dissolved elements in leachates (membrane filtered) were determined with ICP-AES. The mixtures after 3 and 6 months were destructively sampled for elemental analysis and pyrophosphate, oxalate, and dithionite-citrate sequential extractions. The (first 4-weeks) results showed the amounts of Si, Ca, and Mg released from small basalt alone were 2-3 folds higher, and those of Fe and Al were similar to 1.5 folds higher compared to large basalt, implying greater CO<sub>2</sub> removal by smaller basalt. After 3 and 6 months, small basalt mixtures (SBM) tended to retain more total C than large basalt mixtures (LBM). Similarly, SBM showed higher contents of extractable Fe, Al, and Mg. These results are consistent with our hypothesis. However, it is also possible that (i) SBM accumulated more inorganic C and (ii) small and large basalt inherently had slightly different mineralogy. We are currently testing these possibilities by organic C analysis and mineralogical characterizations (XRF, quantitative XRD, TEM/EDX, XANES). We will report these outcomes and also discuss potential effects of basalt addition on organo-mineral aggregation.

#### PEDOGENIC DIVERSITY AND LAND USE SUITABILITY IN NORTHWEST TUNISIA

A. TLILI, F. MLAIKI, I. DRIDI

University of Tunis El Manar, Faculty of Sciences of Tunis, Department of Geology, Tunis, Tunisia, Tunis, TUNISIA

Tunisia (32-38°North; 7-12°East) constitutes the uppermost of North Africa on the Mediterranean basin. This study aims to determine the approximative association between land use and soil type suitability in the Northwest of Tunisia. Indeed, It's a narrow area with contrasting bioclimatic and geological conditions with highly diversified soils. We have acid soils with clay and sandstone alternation, non-calcareous, shallow but quite rich in organic matter; deep calcareous soils on marl slopes; shallow soils on calcareous rock. The World Reference Base (WRB) was used to classify soil profiles. The most accurate representations of the soil types in the studied area are Lithosols (318000ha), Chromic Luvisols (234000ha), Calcaric Fluvisols (204000ha), Calcaric Cambisols (36000ha), Rendzinas (3000ha). Lithosols are limited by the rockiness and stoniness of the substratum. They are suitable for olives and vines. In most cases, this soil type is not suitable for agriculture and should be left under natural vegetation. Chromic Luvisols are relatively poor in organic matter and phosphorus. They are used for winter cereals and olive groves. However, lack of water is the main obstacle. Calcaric Fluvisols are well endowed with exchangeable bases and with total P<sub>2</sub>O<sub>5</sub>. They constitute a fertile agricultural area densely occupied by food crops. Calcic Cambisols have a good mineral reserve and its suitability depends essentially on texture, which determines water retention capacity. They are used for winter cereals. Olives and figs are also grown, and, less frequently, citrus. But, hilly topography and an abundance of calcareous crusts are a barrier to development. Rendzinas are rich and have a high humus content. They are suitable only for the cultivation of olives, figs and vines. Moderate slopes can be suitable for winter cereals (wheat and barley) and winter pastures. Furthermore, Northern Tunisia faces various soil degradation. For example, Erosion removes topsoil, the most fertile and nutrient-rich layer. Irrigation with poor water quality, use of improper cultural practices or inadequate drainage lead to salinization.

<sup>2</sup> Boreal Mapping, Bologna, ITALY

<sup>3</sup> National Academy of Agriculture, Bologna, ITALY

Both monitoring and assessment of ecosystems and their interactions play pivotal roles in the journey toward the effective management of both natural and agricultural lands. Among the crucial components of terrestrial ecosystems, soil stands out as a fundamental entity, recognized globally as one of the most intricate and diverse natural systems, where processes like the nutrients cycle and water regulation take place, and most of the terrestrial carbon is stored. Despite its paramount importance in sustaining biodiversity and providing essential ecosystem services, the ecological studies and policy-making processes for environmental protection and management often neglect the significant role of soil. Soil development is a complex process influenced by various environmental factors, including climate, organisms, parent material, morphology, and time, and the interaction with different biodiversity-bearing sectors is obvious. Intrinsic (within soil itself) and extrinsic (environmental) factors influence the pedodiversity at various scales. GIS-based analyses offer a powerful tool to process this amalgamation of factors, allowing the formulation of landscape units. These units represent distinct fractions of an area characterized by a unique combination of soil-forming factors. Consequently, landscape units can serve as a base to plan survey campaigns and for mapping the pedodiversity and ecosystems services of soils. This approach not only optimizes soil survey campaigns but also yields comprehensive cartographic documents. With this contribution, we elaborate on the workflow involved in creating the soil map (1:50000) of the Frignano Regional Park in northern Italy. In this area, the seventeen landscape units harbored eleven great groups from five soil orders: Inceptisols, Entisols, Alfisols, Spodosols, and Histosols. Furthermore, we highlight the potential of this mapping process in ecosystem assessment, monitoring, and management, and the role of pedodiversity in sustaining a biodiverse environment. The systematic integration of these methodologies enhances our ability to make informed decisions for the sustainable stewardship of natural resources within the intricate web of terrestrial ecosystems.

<sup>3</sup> RESEARCH CENTRE FOR VITICULTURE AND OENOLOGY, COUNCIL FOR AGRICULTURAL RESEARCH AND ECONOMICS, GORIZIA, ITALY

<sup>4</sup> RESEARCH CENTRE FOR AGRICULTURE AND ENVIRONMENT, COUNCIL FOR AGRICULTURAL RESEARCH AND ECONOMICS, FIRENZE, ITALY

Halophytes are plants that evolved mechanisms to tolerate and survive in coastal areas characterized by adverse conditions due to salt accumulation and seasonal anoxia. Most of these mechanisms are implemented in the root and rhizosphere, involving the accumulation of organic and inorganic compounds that promote soil microbial activity and enzyme secretion. The resistance capacity has been widely investigated in controlled conditions and/or on soil samples collected at standard depths, omitting the influence of soil genetic horizons properties. Therefore, this study aimed to investigate the adaptation mechanisms of two halophyte plants [*Arthrocaulon macrostachyum* (Moric.) Piirainen & G. Kadereit and *Juncus maritimus* Lam] in response to salt and hypoxia stress condition in a salt marsh located in the Po River delta regional park, central-north Italy. Specifically, bulk and rhizosphere soil were considered to detect the changes in chemical, physical, and biochemical properties of genetic horizons (Az, Bgz, and 2Bgz).

In the Az horizon, results suggested a salinity-resistance capacity depending on plant species due to different ions absorption (*A. macrostachyum*) and secretion of organic compounds (*J. maritimus*), though the negligible rhizosphere activity. Contrary, most of the investigated enzymes recorded higher potential activity in the rhizosphere than in the bulk soil of the Bgz horizon. The rise of the water table resulting in saturated conditions and root hypoxia may affect enzyme activity. Thus, halophytes develop an aerenchyma system that allows gas exchange from shoots to roots, enhancing biochemical activity in the rhizosphere soil. In the 2Bgz horizon, only 8 (TOC, HC, Ca<sup>2+</sup>, Mg<sup>2+</sup>, K<sup>+</sup>, Na<sup>+</sup>, SO<sub>4</sub><sup>3-</sup>, TN) out of 31 soil parameters showed significant differences. Therefore, plants adopt several mechanisms to tolerate stress conditions in the surface horizons interested by high root abundance. Below, soil dynamics are controlled by horizon properties that prevail on plant influence.

<sup>4</sup> National Academy of Agriculture, BOLOGNA, ITALY

A methodological approach is proposed to establish the interrelationship between soil microbial functional diversity to soil development under Udic soil moisture regime with different vegetation cover (Douglas fir, forest beech, grassland). As soil evolution proceeds through an increasing niche separation we expect a link between functional diversity and soil development. Shannon's (H') diversity index was calculated using eight enzyme activities ( $\beta$ -cellobiohydrolase, N-acetyl- $\beta$ -glucosaminidase,  $\beta$ -glucosidase,  $\alpha$ -glucosidase, acid phosphatase, arylsulfatase, xylosidase and butyrate esterase) in order to assess functional diversity at different scales, from soil horizons ( $\alpha$ -diversity) to soil profiles ( $\beta$ -diversity) under different vegetation ( $\gamma$ -diversity) and belonging to different taxonomic subgroups. In addition, the ratio of acid phosphatase to chitinase was calculated as a potential index of soil development. Twenty-five soil profiles were selected in Italian Alps or Northern Apennines in three phytoclimatic zones (Castanetum, Fagetum, Picetum) with Udic soil moisture regimes at three different temperature regimes (Mesic, Frigid and Cryic). The soil under study were classified according to the Soil Service Staff (20214) as follow: 1 Typic Haplocryod, 1 Spodic Dystrudept, 2 Mollic Hapludalfs, 1 Mollic Haplocryept, 2 Typic Hapludalfs, 4 Lithic Dystrudepts, 2 Dystric Eutrudepts, 1 Lithic Cryorthent, 5 Humic Dystrudpets, 1 Humic Lithic Eutrudept, 1 Lithic Udorthent, 2 Lithic Humudepts, 2 Typic Dystrudepts. The lowest profile differentiation, the highest the variability of the values obtained within horizons in the soil profile suggesting a link between soil development and the patterns of enzymatic activity. The microbial functional diversity assessed using Shannon diversity index and phosphatase/chitinase ratio measured at different scales (from  $\alpha$ -diversity to  $\gamma$ -diversity) may represent a methodological approach to establish the interrelationship between pedogenetic processes, soil development and soil microbial functions. In particular, under Udic moisture regime an inverse relationship was found between Shannon Index and soil development. Therefore, soil microbial functional diversity, measured using Shannon diversity index, might be considered linked to the highest entropy of young undeveloped soils.

#### A NOVEL VIEW IN GEOPEDOLOGY: HOW SMALL LANDFORMS FROM PAST LAND USE AFFECT THE PEDOSPHERE

T. RAAB<sup>1</sup>, P. DROHAN<sup>2</sup>, A. RAAB<sup>1</sup>, A. SCHNEIDER<sup>1</sup>, A. BONHAGE<sup>1</sup>

<sup>1</sup> Brandenburg University of Technology Cottbus-Senftenberg (BTU), Cottbus, GERMANY

<sup>2</sup> The Pennsylvania State University, State College, USA

LiDAR-based high-resolution digital elevation models (DEMs) can now provide a centimetre-accurate image of the Earth's surface. Soil science is still in the early stages of realising how fundamentally this new technology will change our understanding of the formation, properties and functions of the pedosphere and in particular the uppermost part of it. By using these DEMs, it is possible to identify and classify small topographic features that were previously not considered in soil mapping. Therefore, precise landform analyses will be crucial in assessing variations in soil horizonation and soil stratigraphy and will provide the framework for a new perspective in Geopedology that truly integrates Geomorphology and Pedology from pedon to soil landscapes. In the digital domain, this geopedological approach is growing rapidly by using artificial intelligence (AI) to automatically identify small landforms and visualise the heterogeneity of diverse pedological information. We present the results of the study of different types of relict anthropogenic landforms (RALs) and highlight their characteristics compared to natural soils. The origins of these relict features can vary greatly, as can their distribution, morphology and age. The analysis of high-resolution relief models shows that morphological features can be found, particularly in forest that were created in pre-industrial times. Settlement structures (e.g. burial sites) or linear relief forms created by soil cultivation (e.g. field terraces, furrow systems) are common. Relict Charcoal Hearths (RCHs), which originate from historic charcoal burning, are usually small circular platforms but can still cover a considerable part of the area. A relatively complex geomorphology can be observed in historic mining areas, which may include different landform types such as mine shafts and spoil heaps, resulting in a very heterogeneous pedological mosaic. To summarise, all studies reveal a high variation of soil properties controlled by small relief structures. Pedology should take this more into account in the future and improve knowledge of the impact of RALs on the pedosphere and other components of ecosystems.

THE APPLICATION OF RARE EARTH ELEMENTS AS PEDOGENIC TRACERS

C Y WU <sup>1</sup>, C Y YANG <sup>1</sup>, M D CASCANTE <sup>1</sup>, W A LIAO <sup>1</sup>, H Z HUM <sup>1</sup>, J Y WU <sup>1</sup>, K F HUANG <sup>2</sup>, Z Y HSEU <sup>1</sup>

<sup>2</sup> Institute of Earth Sciences, Academia Sinica, Taipei, TAIWAN

Rare earth elements (REEs) comprise 15 lanthanides and yttrium exhibiting great resemblances in physiochemical properties due to the similar trivalent chemical affinity, and hence generally occur as a group in the environment. Naturally, the concentration and constitution of REEs in soils are dominated by the parent materials. Nevertheless, the gradually decreasing ionic radius with the increased atomic weight causes the distinct affinities of REEs with organic matters, clay, and iron oxides leading to the fractionation of light REEs (LREEs, Z = 57–64) and heavy REEs (HREE, Z = 39, and 65–71) in soils. During pedogenesis, the fractionation of REEs providing possibilities of applying REEs as pedogenic tracers.

By investigating pedochemical behaviors of REEs in 50 soil pedons derived from felsic/intimidate/mafic igneous, sedimentary, and ultramafic rocks which encompassed diverse soil types attributed by intense pedogenesis processes in Taiwan, we found that the total REEs concentration in the studied soils was  $119 \pm 67.7$  mg/kg. Additionally, the REEs abundance decreased as the following order of parent materials: granite ( $171 \pm 92.9$  mg/kg) > sandstone and shale ( $160 \pm 34.6$  mg/kg) > mafic rocks ( $150 \pm 64.6$  mg/kg) > andesite ( $90.4 \pm 42.6$  mg/kg) > ultramafic rocks ( $55.0 \pm 43.6$  mg/kg), while soils from granite, sandstone and shale, and andesite were relatively enriched in LREEs.

Regardless of the sources, HREEs co-migrated with clay particles, and iron (Fe) oxides in highly weathered pedons. Furthermore, the condensations of HREEs in clay coatings and Fe nodules compared with the soil matrix were identified by the laser ablation inductively coupled plasma mass spectrometry and the electron probe microanalyzer. The preference of secondary minerals for HREEs over LREEs caused preferential downward translocation of HREEs vs. less mobility of LREEs during pedogenesis, indicating in the increasing La<sub>N</sub>/Sm<sub>N</sub> and decreasing Gd<sub>N</sub>/Yb<sub>N</sub> ratios with more advanced soil development. Our results demonstrate that in humid tropical soils, La<sub>N</sub>/Sm<sub>N</sub> and Gd<sub>N</sub>/Yb<sub>N</sub> are capable of quantifying the degree of weathering and illuviation, respectively.

<sup>4</sup> UNIVERSITA DEGLI STUDI DI FIRENZE, DIPARTIMENTO DI SCIENZE E TECNOLOGIE AGRARIE, ALIMENTARI, AMBIENTALI E FORESTALI, FIRENZE, ITALY

The first step in the process of utilizing space resources is to identify them, localize them and assess their distribution, composition, and quantity. In the case of extra-terrestrial terrigenous material, the so-called regolith for many or real soil according to others, all this means mapping it (Certini & Scalenghe, 2010). Indeed, Moon regolith will probably play an analogous role as soil does for our civilization on Earth to provide food and building material for future extra-terrestrial human settlements. The creation of a lunar resource cartography requires to reach a consensus on the language used to communicate on the regolith or soil layers, which is a prerequisite for classification as well. On Earth, pedologists have developed an international nomenclature of soil horizons based on interpretative symbols which allow to immediately link soil description to properties and/or genesis of the described layers. Its development during the 20th century has permitted to develop pedological classification in parallel of the soil mapping process. For the Moon, we propose to use characteristics of the lunar soils such as the  $I_s/FeO$  maturity index of Morris (1978) and the agglutinate content as a first attempt to differentiate soil horizons. Based on those, we propose a labelling system inspired on Earth's pedology concept but adapted to the Moon context. We expect this work to serve as a starting point for discussions between planetary scientists and soil scientists with the aim of building the foundation and concepts of extra-terrestrial soil science to avail of space resources, as already advocated by Cameron in 1963.

#### SOILS AND RARE PLANT HABITAT IN THE COLORADO PLATEAU

J. BOETTINGER<sup>1</sup>, E. SCHUPP<sup>2</sup>

<sup>1</sup> Utah State University, Dept. of Plants, Soils, & Climate, Logan, USA

<sup>2</sup> Utah State University, Dept. of Wildland Resources, Logan, USA

It is common for botanists and plant ecologists to study the soil of rare plants by sampling the soil surface horizon and analyzing pH and a few other chemical properties, often looking for a “silver bullet” to explain rare plant distribution. It is rare in these studies to investigate the whole soil in a landscape context. However, multiple pedological studies of rare plants in the arid and semiarid climate of North America Colorado Plateau reveal a unique soil physical habitat where few other plants exist. These rare, endemic plants adapt and survive in soil environments and edaphic conditions that most plants are unable to survive in, effectively creating a competition-free zone. Shrubby reed-mustard (*Schoenocrambe suffrutescens*), Jones' waxy dogbane (*Cycladenia humilis* var. *jonesii*), Parachute beardtongue (*Penstemon debilis*), and Debeque phacelia (*Phacelia scopulina*) all occur in shallow soils in distinct sedimentary rock strata that can be mapped using remotely sensed and topographic data. Soil physical properties are typically coupled with one or more chemical properties that are challenging for most plants.

<sup>9</sup> University of Çukurova, Department of Landscape Architecture, ADANA, TURKEY

Tarsus, the capital city of classical Cilicia dates back to the prehistoric era as one of the most important sites for the beginning of culture in the Eastern Mediterranean sphere. Located close to the coast, at an alluvial and/or lagoon environment, it provided a tryst for Mark Antony and Cleopatra. The ancient city is underlying a sediment of 350 cm where the contemporary Tarsus grew on. The diffusely stratified layers of the deposited sediment from the Kydnos (Tarsus) river overlying the Roman Road excavation site are located in the heart of the modern city. The sediment is laden with anthropogenic materials. The profile of the soil stratigraphic layers, i.e., pedosedimentary units and/or horizons (PSUs), were described and sampled for physical, chemical, mineralogical, micromorphological and thermo-luminescence analyses seeking pedogenic evidence. The overlying fluvial and/or lagoonal (archaeologically predicted date, about 60 CE) PSUs/Technosols are calcareous and high in available and total phosphorous contents (preliminarily coined as a Phosphatic qualifier or horizon of the Technosol). They have been probably modified by human activity at a settlement area, thus, bearing some historical evidence to suggest that the site was part of the growing city after it was abandoned. Thin sections point to a vigorous biological degradation of the organic residues in the PSUs alongside occasional evidence of physical soil forming processes.

The preliminary conclusion is that sediments of the river Kydnos buried the city of Tarsus, via consecutive depositions, which were periodically settled within an alluvial-lagoonal environment. Historical evidence supported by the interdisciplinary nature of pedology, revealed that the establishment of the modern city of Tarsus at this site probably did not occur until a few hundred years ago. Thus, as soil science's interdisciplinary nature sheds light on the past, its legacy will also continue to do so in the future as the best recorder of earthly processes, as demonstrated by the example of this Roman Technosol.

**SERIFURE (SOIL ECO-REGION INDEX ON FUNCTIONING AND RESILIENCE): A SYNTHESIS INDEX ON SOIL ECO-REGIONS THAT COULD PROVIDE USEFUL INSIGHTS ON SOIL FUNCTIONING AND RESILIENCE**

S. DUMONTET<sup>1</sup>, C. JACOMINI<sup>2</sup>, L. VARONE<sup>3</sup>

<sup>1</sup> Parthenope University, Naples, ITALY

<sup>2</sup> ISPRA CN\_LAB/BIO Soil & Land Ecology Laboratory, Rome, ITALY

<sup>3</sup> Sapienza University of Rome, Rome, ITALY

The theoretical basis underpinning the hydro-eco-region approach is a tool to macro-describe the specific characteristics of water bodies, considering their physical, chemical, environmental and biological characteristics. A similar approach could be used to identify soil macro-characteristics, driven by different environmental drivers, including edaphic fauna, fungi and microorganisms. We propose then to undertake a new holistic soil characterization, aimed at framing soils in a new identification scheme, based on multifaceted approach, having soil communities as major driver. The set of indicators should be targeted to the scale of investigation, and a simplified soil classification such as the FAO World Reference Base for Soil (2022), enriched by a layer of functional traits description of soil communities. We found advisable to choose the upper two horizons, which should grant a sufficient description of the processes that could describe the soil environment in its pedogenic evolutionary dynamics.

At the highest scale, the weighted descriptors should consider available data on fauna, flora, microbiota coupled with some abiotic descriptors. The functional traits to be considered are: food-web interactions, reproductive strategies, dimensions and mobility of the biological elements considered, and the state of soil in its basic components: texture, porosity, water-holding capacity, SOM, CEC, pH, lithological substrate and pedo-climatic factors. A qualitative analysis could take in consideration more characteristics of the soil biota, such as the presence of endemic and rare species, of stenoecious vs. euryoecious taxa, or of specialised organism vs. generalist functional groups.

A test of selected examples with a minimum data set of variables will be set up to validate and discuss the proposed methodology.

The SERIFuRe Index could grant a synthesis of the available characteristics of soil elements, both on the living communities and the abiotic environment where they live, and help identify homogeneous units that could be useful to describe, depict and correctly manage soils throughout the world.

#### DISENTANGLING TANGEL: THE ROLE OF PLANT TRAITS FOR POST-DISTURBANCE HUMUS FORMATION

K. KATZENSTEINER KLAUS<sup>1</sup>, C. ROSINGER<sup>1</sup>, J. SCHAUFLENER<sup>3</sup>, A. GATTESCO<sup>2</sup>, M. MAYER<sup>1</sup>

<sup>1</sup> University of Natural Resources and Life Sciences (BOKU), Department of Forest and Soil Sciences, Vienna, AUSTRIA

<sup>2</sup> University of Natural Resources and Life Sciences (BOKU), Institute of Microbial Genetics, Vienna, AUSTRIA

<sup>3</sup> Austrian Research Centre for Forests, Department of Forest Ecology and Soil, Vienna, AUSTRIA

Mountain forest soils are frequently characterized by thick organic surface layers. On pure limestone or dolomite with no or patchy mineral soil, the forest floor can reach thicknesses of decimetres up to a meter, resulting in a humus form called 'Tangel'. Disturbance, however, can lead to rapid mineralization - in case of wildfires humus even increases fuel load and can burn down to the bedrock. A 'burning' question thus is how fast such humus forms recover. In our case study we investigate vegetation and humus succession in a mountain forest 70 years after a stand replacing fire. Post fire succession as interpreted from aerial images shows a rapid development of grass cover after 3 years. 60 years later, however, patchy regeneration of *Erica carnea*, *Larix decidua*, *Pinus mugo* and *Picea abies* still cover less than half of the burnt site. Soil organic carbon (SOC) stocks in these patches follow a ranking *Larix* < *Pinus* < *Picea* < grass < *Erica* (1.5, 2.4, 2.5, 2.9, 3.0 kg m<sup>-2</sup>, respectively) which, in average is about 35% of SOC stocks in mature reference stands (7.1 kg m<sup>-2</sup>). While under grass SOC is concentrated in mineral soil (50%), forest floor under *Erica* and tree patches contains 85% (*Larix*) to 98 % (*Erica*) of SOC. There is a species effect on aboveground carbon input related to litterfall (*Erica*~*Picea* >> *Larix* > grass), litter quality (widest C/N and C/P ratios for *Erica*), and soil temperature (bare soil ~ grass > *Erica* ~ *Larix* > *Picea*). Moreover, incubation of litter shows pronounced differences in R10 (*Erica* < *Larix* ~ *Picea* << grass) and microbial N per g SOC is particularly low under *Erica* and highest under *Larix*. Soil enzyme activities show distinct differences between species, indicating different mineralization and nutrient acquisition strategies. We conclude that plant traits play a key role particularly in early stages of Tangel formation.

#### CHARACTERIZATION OF SOIL MICROALGAE AND CYANOBACTERIA IN A DIFFERENTIALLY MANAGED OLIVE ORCHARD

R. ADDESSO <sup>1</sup>, C. CRECCHIO <sup>2</sup>, L. LUCINI <sup>3</sup>, A. SOFO <sup>1</sup>

<sup>1</sup> University of Basilicata, Matera, ITALY

<sup>2</sup> University of Bari, Bari, ITALY

<sup>3</sup> University Cattolica Sacro Cuore, Piacenza, ITALY

Soil microalgae and cyanobacteria (SM&C) show potential benefits for sustainable agriculture. They participate to the biogeochemical processes, enriching the soil in biomass, providing nutrients (such as N) essential for plant growth, creating a hospitable microenvironment for plants through bioactive compounds production, and settling synergic interaction with other soil microorganisms. The research aim was to characterize SM&C communities in a Mediterranean olive orchard located in a semi-arid climate (Ferrandina, Basilicata, Italy), subjected to a sustainable (Smng) or conventional (Cmng) land use for 22 years. The SM&C were cultivated in two selective liquid media containing N (for all) and without N (for isolating nitrogen-fixer cyanobacteria). The Smng soils had significantly higher microalgae ( $2.210 \cdot 10^4$  g<sup>-1</sup> soil in Smng and  $0.872 \cdot 10^4$  g<sup>-1</sup> soil in Cmng), and equally for cyanobacteria ( $0.408 \cdot 10^2$  g<sup>-1</sup> soil in Smng and  $0.240 \cdot 10^2$  g<sup>-1</sup> soil in Cmng). Dominant species were detected by light microscopy and 16S/18S/ITS rDNA metagenomics. *Trebouxia*, *Euglena*, *Chaetophora* green algae genres, and the diatom *Cymbella* were predominant in the Cmng soils. On the other hand, *Anabaena* cyanobacterial genus, *Oedogonium* and *Scenedesmus* green algae, and the diatoms *Navicula* and *Pinnularia* were more abundant in the Smng soils. Soil management type caused a different profile of the intra- and extracellular metabolites produced by SM&C, with an evident up-modulation in the Smng soils of the biosynthetic pathways of secondary metabolites, hormones, fatty acids and lipid, some of them with growth-promoting properties. We demonstrated that, besides their several essential ecological functions, SM&C can be applied for maintaining healthy soil and promoting plant growth. This study was carried out within the Agritech National Research Center and received funding from the European Union Next-GenerationEU (PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR) – MISSIONE 4 COMPONENTE 2, INVESTIMENTO 1.4 – D.D. 1032 17/06/2022, CN00000022). <sup>3</sup> Department DAFNAE, University of Padova, Padova, ITALY

Land use changes (e.g. transformation of natural landscapes, forest degradation, and increase in croplands) due to human activities are considered amongst the most influential ecological disturbances affecting soil biodiversity and environmental sustainability. Restoring and managing soil biodiversity requires a better understanding of the determinants of soil biodiversity and how they function. To identify the differences in soil biodiversity of natural and anthropogenic ecosystems, we want to compare the community composition, species co-occurrence patterns, and ecological assembly processes of soil microbial communities in a paired setting featuring a natural and an anthropogenic ecosystem facing each other at identical climatic, pedological, and vegetational conditions. To achieve this goal, two pairs of relatively closed and small-island systems were chosen in Italy and China. The Italy field survey was carried out at two adjacent strips of land within the Po River delta lagoon system (Veneto, Italy), one of which is protected within a natural preserve and the other has been converted for decades into a tourist resort. The China field survey was carried out on a natural preserve island and an island heavily occupied by agriculture and industry of Guangdong–Hong Kong–Macao Greater Bay Area. This study aimed 1) to identify how the soil bacterial and fungal diversity, abundance, and community composition change under different anthropogenic disturbances (e.g. settlement, agriculture, and industrial); 2) to investigate what specific mechanisms allow certain microbes to persist under anthropogenic pressures or environmental modifications; 3) to evaluate microbial diversity changes impact the ecological function and stability in anthropogenic ecosystems.

HUMUS FORMS AND ORGANIC MATTER DECOMPOSITION IN THE SWISS ALPS

S. SEMERARO, M. FAZZARI, P. KIPF, S. RASMANN, R.-. LE BAYON

Institute of Biology - Functional Ecology Laboratory, University of Neuchâtel, Neuchâtel, SWITZERLAND

Along with the current climatic crisis, terrestrial ecosystems are undergoing significant modifications, both above and below ground. The steep elevation gradients of the European Alps might be particularly concerning because of their close connection to temperature gradients. Climate, plants, and soil decomposers influence humus forms and organic matter decomposition. Yet, whether different humus forms could be experimentally linked to litter decomposition remains to be fully assessed. To highlight the link between humus systems and organic matter decomposition, we worked in two regions of the Swiss Alps (Valais and Ticino) along elevational gradients by following a north/south exposure design. We quantified humus forms macrorests proportion types by the Ponge small-volume method and measured the decomposition of green tea and rooibos tea within the Para- and Terro-humus systems. We found that Parasystems and Terrosystems differed in tea decomposition rates, with a slower decomposition in Parasystems than in Terrosystems. We also observed that elevation, and hence, vegetation type (i.e., forest in the subalpine versus grassland in the alpine), drove humus form distribution, with Parasystems found in the alpine and subalpine in Ticino, while in Valais Parasystems were only found in the alpine and Terrosystems in the subalpine levels. Further analyses are, however, needed to identify other variables that best correlate with variation in decomposition processes within humus systems, such as soil decomposer community composition.

### CARBON STORAGE IN THE FOREST FLOOR AND SOIL IN A PRIMARY BEECH-FIR FOREST

D. BAKSIC, N. BAKSIC, S. MIKAC

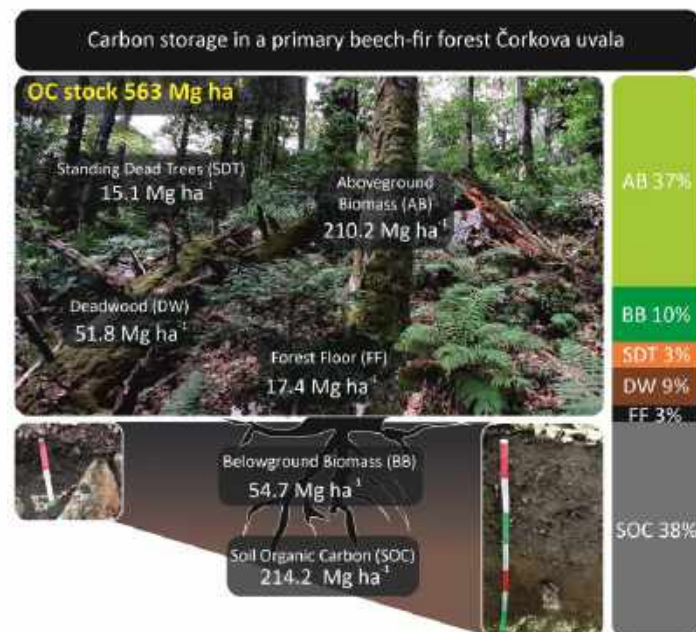

University of Zagreb, Faculty of Forestry and Wood Technology, Zagreb, CROATIA

Primary and old-growth forests play a very important role in carbon sequestration and storage and thus makes an important contribution to global efforts to mitigate climate change. These forests serve as a benchmark or reference point due to their ability to store and accumulate carbon over time and are used to compare and evaluate the effectiveness of different forest management practices, conservation strategies and restoration measures.

The aim of this study was to determine the carbon stocks in the forest floor and soil and other C pools in the primary Dinaric beech-fir forest Čorkova uvala in the Plitvice Lakes National Park, which covers an area of 80.50 ha between 860 and 1028 m asl. The average annual temperature is 9.4 °C and the average annual precipitation is 1592 mm. The area is characterized by the typical karst relief. The predominant soil type is Leptic Cambisol, alternating with Mollic Leptosol, while Luvisol occasionally occurs at the bottom of the sinkholes. The trees are around 450 years old. Sampling of the forest floor (FF) was carried out by layers along the transect, while the soil was sampled in a systematic grid.

On rocky and stony areas, there is no FF at all. Where the FF was shallow, i.e. about 1 cm thick, its mass was 11.7 Mg/ha (4.9 Mg C/ha), and in some places the thickness of the FF reached almost 9 cm, i.e. the mass was 94.6 Mg/ha (48.7 Mg C/ha). The amount of C stored in the soil varied from 37.9 Mg/ha to 490.6 Mg/ha.

We have developed regression equations that relate the mass of the FF and C stock to its depth. The bulk density (BD) values obtained can also be used to convert depth measurements into mass and C stocks for each layer and the entire forest floor. The obtained data were compared with data for managed beech-fir forests and will be presented to the Congress.

**Keywords:** carbon storage, forest floor, soil, beech-fir primary forest

#### CHEMICAL AND MINERALOGICAL EVOLUTION OF KIMBERLITE MINE TAILINGS - A STUDY ON THE PEDOGENETIC PROCESSES THAT CONVERTS ULTRAMAFIC MINE WASTE TO FUNCTIONAL SOILS

J. KOCH, L. VAN DER MERWE

<sup>1</sup> North-West University, POTCHEFSTROOM, SOUTH AFRICA

Kimberlites are plutonic igneous rocks rich in ultramafic minerals. Their formation is the product of solidified melts that intruded into the Earth's mantle because of pressured magma flowing via fractures and rising to the crust. Kimberlites are petrographically complex aggregates with a wide variety of chemical compositions, and they may contain diamonds as a rare component giving them a high economic value. The exposure of kimberlite mine waste to environmental conditions leads to geochemical reactions that change the chemical composition of the primary rock. These changes impact the morphological features of the waste, leading to the formation of new soil layers.

The study focuses on the kimberlite waste located in the North-West province of South Africa. The intended resource is extracted mechanically, meaning there are little to no added chemicals present in the mine waste. However, because kimberlites are primarily composed of silica-rich, iron oxides, magnesia, and alumina-rich minerals they are easily weathered. The investigation of elemental fluctuations using P-XRF highlighted the influence of particle size, depositional layering, and illuviation on the abundance of specific elements. The XRD analysis provided insight into the mineralogical composition of the soil samples, distinguishing between primary and secondary minerals and their distribution in the sampled profiles. The presence of minerals such as quartz, mica, amphibole, pyroxene, and olivine in the primary mineral category, and secondary minerals including; chlorite, kaolinite, vermiculite, calcite, and gypsum, illustrated the transformation and weathering processes within the waste material. Lastly, petrographic microscopy analysis revealed the ongoing processes of decomposition, disintegration of mineral fragments, and the presence of organic matter and water-soil interactions, all of which play a significant role in the formation of a new soil profile.

Forest soils harbor a vast array of organisms that, through their trophic interactions, drive and shape the carbon flow and give rise to ecosystem functioning. The transfer of carbon throughout the soil food web depends not only on the abundance of organisms but also on the number of functional groups involved. Understanding how functional groups shape carbon flows is crucial to disentangling the role of functional diversity in soil processes. In this work, soil food webs were represented using trophic network models of two beech forests in spring and autumn, which were assembled and mass-balanced by quantifying carbon flows between their components. Employing network analysis, models were investigated aiming to identify the role of the components on carbon flow, cycling, and functional trophic relationships. Moreover, we explored how the structure of carbon exchanges between components promotes efficiency and stability.

Results indicate that the carbon requirements of each trophic group highly depend on indirect interactions and carbon cycling. Specific groups such as Collembola play the role of hubs in distributing carbon. Indirect interactions often reverse the impacts of direct trophic relationships being antagonistic to the direction of change predicted based on predator–prey interactions. The presence of generalist feeding habits causes the redundancy of energy channels and increases the resilience of food webs making them more efficient in absorbing perturbations but at the expense of transferring carbon efficiently. Although differences can be observed across sites and periods, food web structure rather than environmental variability seems to be the main factor responsible for patterns of carbon flows in the two beech forests.

#### EFFICIENT PHOSPHATE RECOVERY FROM WASTEWATER AND REUSE AS FERTILIZER USING IRON-OXIDE-CLAY COMPOSITES.

A. RADIAN, N. LAPID-PEREZ, H. GANEM, O. GILOR, K. COHEN

Technion, Haifa, ISRAEL

Phosphate fertilizer is in growing demand, however, the declining natural resources and the secondary environmental pollution from overuse and effluent disposal necessitate the development of sustainable phosphate (P) removal methods that allow for proper nutrient recovery with minimal energy and chemical strains. This study highlights the ability of montmorillonite (MMT) clay decorated with amorphous iron oxide nanoparticles (FeOx-MMT) to specifically recover P from wastewater and allow for easy regeneration of the surface and potential use as fertilizer when spent. The nano-sized iron-oxides deposited on the MMT show high adsorption affinity towards P due to the increase in reactivity and surface area. Batch experiments showed rapid adsorption with equilibrium reached after ~1.5 hrs. at neutral pH. Isotherms were fitted to the Langmuir model and capacity was determined to be 5.63 mg-P/gr composite or 92.3 mg-P/gr-Fe. The reaction was most efficient at acidic pH (4) and high ionic strength. Desorption experiments revealed very small hysteresis and high reversibility of the reaction even at neutral pH. Continuous column experiments were performed and compared to a commercially available product, granulated iron hydroxide. The results highlighted that the composite was able to remove higher P concentrations per g Fe and was far more regenerable than the commercial alternative over five cycles. Finally, the spent composites that were added as fertilizer to sandy soil exhibited P activity similar to the commercial fertilizer yet, almost no leaching was observed. Thus, this natural clay-based material can help alleviate P pollution in soil and water, while maintaining soil health and fertility.

#### P RECOVERY FROM WASTEWATER & REUSE AS FERTILIZER IN THE SOIL

<sup>4</sup> Norwegian University of Life Science, Faculty of Environmental Sciences and Natural Resource Management, As, NORWAY

Saltwater contamination is a major contributor to agricultural soil degradation. With rising sea levels and increasing dry periods due to climate change, ground water in temperate coastal areas is becoming increasingly brackish, forcing growers to use part-saline ground water to irrigate their crops in summer. In arid areas, saltwater contamination has been reported to decrease crop yields, but the short- and long-term effects of saltwater contamination in temperate areas have not yet been thoroughly investigated, especially its effects on the soil microbial communities. Here we developed a 3-year experiment to study the yearly effects of different levels of saltwater irrigation on crops and soil microorganisms. Concerning the crops after the first year, our results show that higher level of salinity (6 dS/m and 9 dS/m) have a negative impact on crop yield, while medium level of salinity (3 dS/m) has no negative impact on crop yield compared to the control. However, after 2 years of experiment, our results demonstrate a drastic decrease in crop yield between the control and saltwater irrigation, even for the medium salinity level. Concerning the microbial communities after the first year, our results demonstrate that increasing the salinity level in water has an impact on the soil microbial communities compared to the control. This experiment will be very useful to growers to help them decide how much and for how long they can safely use part-saline water to irrigate their crops, in order to reduce their costs without decreasing their yield or harming the soil microbial community.

##### ANALYSIS OF EARTHWORMS AND SOIL QUALITY IN A LONG-TERM WETLAND WITHIN AN AGRICULTURAL CONTEXT

F. GAVINELLI, V. GIANNINI, M. BORIN, G. CONCHERI

Department of Agronomy, Food, Natural Resources, Animals and Environment (DAFNAE), Università degli Studi di Padova, PADOVA, ITALY

Wetlands represent crucial ecosystems, playing a significant role in maintaining biodiversity and purifying water. This study analysed the biodiversity status of a wetland area used for 30 years for drainage and phytodepuration purposes within the Experimental Agricultural Farm 'L. Toniolo' at the University of Padua. Covering an area of one hectare and having undergone no cultivation over the years, it is characterized by dense woody shrub areas and other herbaceous parts. Semi-natural conditions and conservational features were evaluated using standardized and innovative sampling and analysis methods.

Physicochemical, microbiological, and soil fertility parameters were studied, aided by earthworm fauna analysis as a driver for soil conservation. Specifically, the earthworms collected were identified, and their distribution and abundance concerning spatial variations within the area were evaluated.

The results revealed a rich diversity of earthworms, with a significant prevalence of endogeic species, particularly abundant in woody-shrub areas. Spatial variation analysis highlighted differences in earthworm community composition among different parts of the wetland, suggesting an association between the distribution of these species and micro-environmental variations.

This work highlights the importance of the presence of semi-natural and humid areas, with drainage and phytoremediation purposes or as simple buffer areas, in agricultural contexts as they can act as sites that contribute to the resilience of agricultural territories also through the increase in biodiversity.

##### MITIGATING SOIL COMPACTION: ASSESSING AMENDMENT IMPACT FOR SUSTAINABLE SOIL MANAGEMENT IN GRASSLANDS

E LEPORE <sup>1,2</sup>, D WALL <sup>1</sup>, O FENTON <sup>1</sup>, O SCHMIDT <sup>2</sup>, S TRACY <sup>2</sup>, G BONDI <sup>1</sup>

<sup>1</sup> Teagasc, Environment Research Centre, Johnstown Castle, Wexford, IRELAND

<sup>2</sup> University College Dublin, School of Agriculture and Food Science, Dublin, IRELAND

Agricultural activities involving heavy machinery often cause soil compaction, a major issue in global grassland management affecting 33 million hectares in Europe only. High axle loads and ground pressure during machinery operations, like slurry application, induce severe compaction, especially in wet soil. Soil compaction from heavy machinery operations results in reduced grass growth, nutrient uptake, and increased overland flow, impacting nutrient absorption. Ongoing efforts focus on environmentally friendly strategies to improve compacted soil physical properties. However, the impact of organic and inorganic amendments on soil physical properties under varying moisture conditions remains unclear.

Therefore, the present study assesses the remediation properties of slurry, farmyard manure and agricultural gypsum on soil physical status in a compacted Irish grassland. Prior to amendments application, 7x3 meter plots underwent compaction during a year of grassland management, involving four machinery trafficking events at three soil moisture deficit (SMD): + 10 (Dry), 0 (Moist) , and -10 (Wet) mm. Plots received slurry (33 m<sup>3</sup> ha), farmyard manure (50 ton ha<sup>-1</sup>), or agricultural gypsum (1 ton ha<sup>-1</sup>), and were compared to non-compacted amended plots (NC) and a control (C) without compaction or amendment.

Six and twelve months post-amendments application, bulk density samples were extracted under tractor tire marks at three depths (0-10, 10-20, and 20-30 cm). Additional soil cores (10 x 5 cm) were obtained from the topsoil to measure pore size, shape, and connectivity through X-ray Computed Tomography. Dry matter yield samples were collected every four months to assess the short-term effects of the treatments.

Preliminary results at 6 months post-amendments application showed that farmyard manure was effective in ameliorating the compacted 0-10 cm, resulting in a 19% reduction in soil bulk density under Moist and Wet soil conditions. Within the 10 - 20 cm layer, gypsum had comparable efficacy to farmyard manure, yielding an 11% decrease in soil bulk density. As this study remains ongoing, further details will be provided as the results become available.

##### THE ROLE OF WATER USER ASSOCIATIONS IN IMPLEMENTING NATURAL WATER RETENTION MEASURES: A NATIONAL SURVEY

M. RUBERTO, M. FERRIGNO, V. MANGANIELLO, R. PERGAMO, S. BARALLA

CREA Council for Agricultural Research and Economics, Research Centre for Agricultural Policies and Bioeconomy (CREA PB), ROME, ITALY

Natural Water Retention Measures (NWRM) are Nature Based solutions applied to the water sector. They follow the ecosystem approach, which is outlined in the Convention on Biological Diversity [2] and recognised as the most appropriate for water management [2]. There are many links between Water Framework Directive (WFD) and the ecosystem approach. NWRM address several elements of ecosystems at the same time. They are multi-functional measures that aim to enhance and maintain the water retention capacity of aquifers, soils, and ecosystems to improve their status. NWRM can provide multiple benefits, including the reduction of risk of flood and drought risk reduction, water quality improvement, groundwater recharge and habitat improvement [3].

In Italy, Water User Associations (WUAs) can play a key role in ecosystems conservation, especially in irrigated agro-ecosystems. Until the 1990s their role was mainly to create productive areas; then it expanded towards the protection of the environment and water-related ecosystems, through the renaturation of water courses, phytodepuration, creation and management of wetlands etc. [4].

For the economic analysis of the 2021-2027 River Basin Management Plans (RBMP) under art. 5 of the WFD, and as part of the technical support to the Ministry of Agriculture for the coordination of environmental and agricultural water related policies, CREA PB carried out a survey of the measures implemented by WUAs that have a positive impact on water bodies.
